Preface

The tables published in this book form a link in a chain of related intellectual work that has been characteristic of the Office of Population Research since its establishment nearly 50 years ago. One of the authors was first involved in 1941 in analyzing patterns of mortality and constructing model life tables as a research assistant when the Office was preparing a series of books on the population of Europe for the League of Nations. Over the years George Barclay, William Brass, John Hajnal, Karol Krotki, Alvaro Lopez, Norman Ryder, George Stolnitz, James Trussell, C. Y. Tye, Pravin Visaria, and Melvin Zelnik maintained the Office tradition of research on the analysis of fertility and mortality as related to population growth and composition, a tradition that originated in the teaching and guidance of Frank W. Notestein, the director of the Office from 1936 to 1959.

In addition to the general debt we owe our predecessors and colleagues, we acknowledge gratefully the special value to the project of the work of Professor George Stolnitz, who collected and analyzed a large part of the mortality records upon which the model life tables are based. Mrs. Erna Härm, a research assistant at the Office, devoted many months of patient work to the calculation of a preliminary set of model life tables, and to using the preliminary tables to find patterns of deviation that subsequently provided the basis for the four "families" of regional tables that constitute the body of this book.

A special purpose that led to the calculation of these tables was to provide a means of estimating population parameters in a study of the demography of Tropical Africa. It was as a member of the staff of this project that Demeny prepared the programs for the computation of the model tables. Thus some of the cost of devising these tables was provided by the Population Council's generous support of the African project from funds originating in the Carnegie Corporation. The project would not have been possible without the sustaining funds for the whole program of the Office of Population Research provided by the Rockefeller Foun-

dation and the Milbank Memorial Fund. The computer facilities of Princeton University by which these tables were calculated are supported in part by the National Science Foundation (NSF-GP579).

This second edition of *Regional Model Life Tables and Stable Populations* includes additional entries in which deaths and population at ages above 80 are subdivided into five-year intervals. This extension was facilitated by research on old-age mortality in 1979–1981 by Shiro Horiuchi, a member of the research staff at the Office of Population Research, and by Neil Bennett, who developed a number of useful adjustments for this upper end of the age range as part of the research for his doctoral dissertation. Barbara Vaughan programmed the calculations for the extended life tables and stable populations. Research on old-age mortality, and the consequent new computations, were supported by a grant from the National Institutes of Health, Grant No. 5 R01 HD11720–03.

PART I

Description and Explanation

This second edition of *Regional Model Life Tables and Stable Populations* incorporates an extension in range of the original tables, an extension that will be particularly useful in applications to populations with low mortality. In the first edition, the model tables terminated with an open interval beginning at age 80, for persons and deaths. Sometimes deaths and populations beyond age 80 are of little demographic interest because there are so few survivors to age 80 at moderate to high mortality, and because only a very small fraction of the population is found at advanced ages in populations with high fertility. In the lowest mortality model life tables, however, the proportion surviving from birth to age 80 is over 50%, and in low-fertility populations the fraction of the population over 80 can be comparable to the fraction under 10. The absence of information above age 80 in the first edition is therefore a potential handicap in applications to modern low mortality populations. Moreover, the highest expectation of life at birth represented in the first edition of model life tables (77½ years) has been surpassed in several countries. In this second edition, the life tables and stable populations are tabulated by five-year age intervals to age 100, in all but the highest mortality levels, in which the last five-year tabulation is from 90 to 95. The greatest expectation of life at birth is now 80 years (for females) rather than 77.5.

In the construction of new tables for this second edition, a conscious decision was made to avoid unnecessary changes, so that in most applications the second edition yields calculations differing little, if at all, from calculations derived from the first edition. The underlying structure of the mortality schedules up to age 80 is unchanged. Modification of the life tables above age 80 alters the expectation of life at birth by only a small fraction of a year. To maintain model life tables at the same intervals (increments of 2.5 years in expectation of life at age zero for females, beginning with an e_0° of 20 years), it was necessary to compensate for the slightly different mortality above age 80 by very slightly different mortality rates at each age below 80. The values tabulated up to 80 in the

first edition (e.g., of ${}_nq_x$ or l_x) can be exactly recovered by interpolation between entries published here, but given values up to age 80 are accompanied by a slightly different e_0°.

The tables in this volume can expedite a wide range of both demographic analysis and estimation of population statistics. The tables presented here are two principal forms: model life tables and model stable populations. Both forms play a prominent role in recent scientific work on population.

Since the first edition of *Model Life Tables* was published, a number of other sets of model life tables have appeared in print. William Brass devised a flexible method of constructing alternative model life tables by transforming a "standard" l_x function, using the logit transformation.[1] Sully Lederman calculated model life tables by employing statistical relations of mortality rates to different parameters taken as known.[2] More recently, the Population Division of the United Nations has constructed tables derived from mortality schedules in selected less developed countries.[3]

CHAPTER 1

Models of Mortality and Age Composition

A. MODEL LIFE TABLES

> Whereas we have found, that of 100 quick Conceptions about 36 of them die before they be six years old, and that perhaps but one surviveth 76, we, having seven Decads between six and 76, we sought six mean proportional numbers between 64, the remainder, living at six years, and the one, which survives 76, and finde, that the numbers following are practically near enough to the truth; for men do not die in exact Proportions, nor in Fractions: from whence arises this Table following.
>
> JOHN GRAUNT, 1662

Life tables provide a succinct description of what is the most prominent aspect of the state of human mortality: they show the varying chances of dying as a function of age. Basic though such a description might seem, even a superficial check on the existing life tables computed from direct statistical information is sufficient to establish the fact that the available documentation is severely limited. The limitations pertain not only to the quality of the available material, but to its geographic and historical coverage as well.

It is these limitations that constitute both the primary justification and the main weakness of an attempt to construct life tables reflecting generalized experience. Model life tables are necessarily intended for use chiefly in situations where no reliable direct information is at hand; yet the very lack of data for a given population renders the imposition of a model mortality pattern a risky enterprise. It follows from these considerations that the quest for "typical" age patterns of mortality to be incorporated in a family of model life tables should take acount of the full range of variation in the documented patterns, but only after that documentation has been subjected to a critical examination as to its reliability.

The limitations of the potential source material for the construction of model life tables can be readily appreciated by recalling a few historical facts. Although death must have always been among the preoccupations of man, it was not until the mid-17th century that the patterns of regularities in the chance of dying were subjected to scientific investigation. It is in John Graunt's celebrated *Observations*[1] on the Bills of Mortality of London that we find the first sketch of what later came to be called a life table. Its contents, with the exception of the ingenious estimate of the magnitude of child mortality, were purely conjectural; however, its form set the precedent for the death—and survivors—columns of all future life tables. It was Graunt's table that prompted the astronomer Halley some forty years later to construct the first modern life table, that of the city of Breslau for the years 1687—1691.[2] "At least 'tis desired"—Halley wrote in the closing lines of his remarkable exposition—"that in imitation hereof the Curious in other Cities would attempt something of the same nature, than which nothing perhaps can be more

useful." In fact, it was over forty years before the construction of another table was undertaken: Kresseboom's calculations based on records of life annuities in Holland appeared in 1738, and the famous tables of Deparcieux were published in 1746. But from around 1750 these efforts were indeed followed by ever more frequent attempts to obtain measures of mortality, and the life table gradually came to occupy a central place in population studies as a device of description and as an analytical tool.[3]

Although the value of the early tables, not only as pioneering efforts but also as sources of demographic information, is unquestionable, a common weakness they share is the deficiency of the raw statistical material that they incorporate. From the viewpoint of the type of statistical information used, we can distinguish three broad classes of life tables. The first consists of tables based on data supplied by continuous registration systems, such as births and deaths registered by civil or ecclesiastical authorities, hospital records, or records of burials and baptisms. Practically all of the early life tables are based on information of this sort. It is true that such records of births and deaths had frequently preceded the efforts to use them for statistical purposes by many years (e.g., such records were kept both in London and in Breslau, the source of Graunt's and Halley's analyses, as early as the last years of the 16th century), and thus in many cases these records had attained a reasonable degree of reliability. Where a classification of deaths by age was also available (as was the case, e.g., in Breslau but not in London), a good estimate of the true mortality conditions could be obtained, provided that the age distribution of the population was close to a stationary one, since in such a case the age distribution of deaths is approximately identical to the d_x column of the life table. The crucial condition, that the population must be near stationary, was already recognized and clearly stated by Halley. However, a deviation from this condition—particularly if it is due to migration, which was likely to be the case with data relating to urban populations—introduces a difficulty for which ordinarily no satisfactory solution can be found. Furthermore, the omnipresence of age misstatements and the frequent occurrence of age-differential omissions in these bodies of data, and, in many cases, the smallness of totals on which the calculations were based, excludes the possibility of using these life tables for the purposes of generalizing on mortality conditions unless the validity of each table is carefully analyzed: an undertaking that would have exceeded the limits of the present study. Thus, all life tables of the above described type were barred from further consideration as a basis for constructing model life tables.

A second class of tables is made up by life tables constructed from census information alone. If a given cohort that belongs to a closed population is enumerated at two points of time a survivorship rate can be calculated: such rates if based on censuses taken not too far apart in time can be used to calculate a life table, excepting the youngest ages. A number of non-European countries with no tradition of vital registration or with very inadequate birth and death records has censuses permitting such calculations; particularly notable among the resulting life tables are those for India and Egypt. An examination of the reported census age distributions in these countries indicates, however, that drastic adjustments have been necessary before realistic survivorship ratios could be calculated, and, therefore, little reliance can be placed on the precise shape of the life table functions so obtained. The same argument holds if the calculation is based on a single census via inflating the reported age distribution by an exponential of the form e^{ra} (a denotes the attained age and r denotes the growth rate, the latter presumed to be stable). Furthermore, infant and childhood mortality must be estimated for such tables on the basis of separate methods, none of which is likely to give satisfactory results, or which simply repeat experience recorded elsewhere. It was decided, therefore, that no life table of this type would be considered for the purpose of constructing model life tables.

The above reasoning thus led us to construct our study by considering only life tables of the third type: those calculated on the basis of the joint use of data originating (a) from continuous registration and (b) from an enumeration of the population at a given time. The first table of this kind was derived by Wargentin for the years 1755–1763 from the records of Sweden; but in other parts of Northern and Western Europe appropriate data became available only during the first part of the 19th century. The list of populations for which such life tables exist continued to expand during the past hundred years, and now it includes at least some populations from each continent. Up to the present, however, the majority of the world's population continues to live in countries where either vital statistics or censuses, or both, are lacking, and hence the majority lacks the statistical data that would permit the calculation of life tables of sufficient quality to serve as a basis for model tables.

A large collection of life tables of the third type has

[3] For a survey see Harald Westergaard, *Contributions to the History of Statistics*, London, 1932.

TABLE I. Distribution of 326 selected life tables according to year of origin and geographic location

Continent	*Midpoint of reference period of life table*				
	Before 1870	*1871–1918*	*1919–1945*	*After 1945*	*Total*
Africa			5	10	15

America, Latin		7	10	16	33
Asia		7	9	16	32
Europe	23	63	62	58	206
Oceania		10	6	6	22
Total	23	90	99	114	326

been assembled at the Office of Population Research of Princeton University, taken partly from various secondary sources, and partly from original publications of national statistical bureaus. Before accepting this collection as a potential basis for constructing model life tables, some further selection was necessary. First, since uniformity of the data was obviously required, the lack of separate treatment of the two sexes eliminated a table from further consideration; similarly, the availability of life table values (or the possibility to compute life table values) for five-year age groups, with separate groups for age 0 and age 1–4, was required for inclusion. Second, while the collection of tables was necessarily unbalanced both according to its geographical coverage and to the year of origin of the tables contained, it was thought desirable to reduce this imbalance by excluding many life tables from the past few decades that were obviously repetitive in character, such as life tables referring to consecutive intercensal years routinely calculated in some countries. Third, tables covering years in which a country was in a major war were eliminated. Fourth, it was decided to use life tables representing the experience of whole countries only, partly because of the belief that the general quality of the life tables for subregions within countries is less satisfactory, partly, again, to reduce imbalance and repetitiveness. Thus, the large collections of life tables for the individual states of the United States were excluded. This rule was relaxed in a few instances only when the experience of a subregion showed distinct characteristics that persisted over time: this was the case in particular with the tables for Southern Italy that were kept in the collection separately. Some of the German states of the 19th century represented by individual tables were also retained. A few life tables refer to a nongeographically defined subgroup of the population, because of the nonavailability or the lesser accuracy of the data for the remainder: life tables for the United States and New Zealand are those for the white population only.

After the eliminations outlined above a basic collection was obtained containing 326 male and 326 female life tables. The distribution of these tables according to year of origin and geographic location is shown in Table I. These figures bear out the extreme paucity of adequate mortality information for Africa, Asia, and Latin America, and at the same time indirectly show the extraordinary interest of the existing recorded experience. To develop statistical systems that provide data of good reliability is not only a costly but also a very time-consuming process. If one makes the perhaps not too optimistic assumption that currently observed declining mortality trends the world over will continue in the foreseeable future, one realizes the uniqueness of the accurate records—mostly those of European countries before World I—that reflect relatively high levels of mortality. This was then the raw material from which the investigation of age patterns of mortality started.

Generally speaking, two approaches to describe such patterns can be envisaged. The first approach is to find some mathematical expression valid for all ages and thus to formulate what in an earlier parlance was often called a "law of mortality." The first such attempt was made as far back as 1725 by the Huguenot mathematician DeMoivre, who, on studying Halley's table, conjectured that the human survivorship function decreases in an arithmetic progression.[4] DeMoivre's hypothesis was soon disproved, and the first sophisticated step was taken a hundred years later by Gompertz, who advanced his well-known formula (later modified by Makeham) that found extensive application in the graduation of the q_x function of recorded life tables showing irregularities from age to

[4] A. DeMoivre, *Annuities on Lives*, London, 1725.

age and in other actuarial work.[5] The Gompertz–Makeham formula was applicable, however, only for about age 30 and over, and later attempts to compress the mortality function over the whole range of the human age span in a single expression were successful only at the cost of an increasing formal complexity that tended to obliterate the obvious analytical advantages that would result.[6]

The alternative approach to describe a typical pattern of mortality is simply to present a series of tables that retain the numerical form of the conventional life table. The use of "model life tables" in a wide sense was practiced during the past two and a half centuries whenever a life table recorded for a given time and place was applied to populations not directly associated with the experience incorporated in that table. Similarly, it can be said that, for example, the life table of Finland for the years 1901–1910 is a "model" of the Finnish mortality experience for that decade in which no individual year was likely to have had the same mortality as depicted by that "model." In the same vein, it can be said that any projection of a population that is carried out by some more or less detailed classification by age involves some adoption of model life tables. Assumptions on the future course of mortality were, moreover, frequently formulated in a way that implicitly involved the construction of age patterns of mortality experienced by no actual population up to the time the projection was made. Typical assumptions of this sort were that a country of relatively high mortality will reach the mortality pattern recorded in another country in a certain number of years, the form of transition being specified in some definite manner, or that age-specific mortality trends as observed in the past in a given country and described by some appropriate fitted curve will continue in the future, etc. An interesting instance of another "model life table" of somewhat limited applicability was that constructed from observed past relations between two series of life tables: those for the population in question and those for another population.[7]

As far as we know, the first attempt to construct a model life table summarizing age patterns of mortality in several countries in a form that could be associated with any arbitrarily specified value of a parameter indicating the level of mortality was carried out at the Office of Population Research in the early 1940s by one of the authors of this volume in a cooperative work.[8] The parameter chosen was expectation of life at age 10; q_x values were determined by linear regression e°_{10}.

In 1955 the Population Branch of the United Nations published a series of model life tables[9] based on a collection of 158 tables for each sex, computed by using parabolic regressions between q_x values of adjacent age groups starting from a specified value of infant mortality. These series, subsequently published in a revised form,[10] have been widely used in research work on the demography of underdeveloped countries. A criticism of the regression technique employed in the United Nations models led to experimentation with life tables in which each q_x value was obtained by a linear regression on infant mortality, using the same source collection as the United Nations.[11] Sully Ledermann developed sets of model life tables based on linear estimation of $\log({}_nq_x)$ from different mortality parameters taken as known—expectation of life at birth, mortality from 0 to 15, from 30 to 50, from 40 to 65, and over 50, and three combinations of two such parameters.[12]

Experimentation with stable population estimates and the resulting desire to take into account the effect of different mortality patterns on such estimates were primarily responsible for the development of the model life tables contained in this volume. They were worked out approximately in their present form during 1960–1962 and were in use in the Office of Population Research since that time, having undergone two revisions in the meantime. The basic approach that was followed was essentially the one used in the 1944 study cited above with the exceptions that two sets of regression equations were calculated to provide a more satisfactory fit, that the underlying source material was much more extensive, and, most

importantly, that within the experience incorporated in the extended source material four types of mortality patterns were identified and developed into four sets of model life tables. The resulting collection is best thought of as four families of one-parameter life tables, available separately for each sex. The one parameter is any arbitrarily selected index of the life table[13] to which any value within the range of human mortality experience can be assigned. The four families have distinct age patterns of mortality—patterns of a "regional" nature that we have named "West," "North," "South," and "East."[14]

B. STABLE POPULATIONS

> Cependant on voit bien, que cette détermination ne sauroit être développée en général: mais, pour chaque hypothèse de mortalité, si l'on calcule le rapport M/N [population/births, or 1/birth rate] pour plusieurs valeurs de n [one plus the intrinsic rate of increase], & qu'on en dresse une table, il sera aisé d'assigner réciproquement pour chaque rapport donné $M:N$, qui exprime la fécondité, l'augmentation annuelle de tous les vivans, qui est la même que celle des naissances.
>
> LEONARD EULER, 1760

Thus did Euler 200 years ago suggest, in effect, the construction of tables of stable populations.[15] Euler appears to have been the first to visualize a closed population experiencing the same mortality risks for many years, and births that change in number in a geometric progression (i.e., change at constant proportionate rate) from year to year. Such a population has an unvarying age distribution, increases at a constant rate, and has constant birth and death rates. It can be termed a stable population (or a Malthusian population, to use a term of Lotka's).[16] The age distribution is given by equation (1):

$$c(a) = be^{-ra}p(a) \tag{1}$$

where $c(a)$ is the proportion of the population at age a, b is the birth rate, r the annual rate of increase, and $p(a)$ the proportion surviving from birth to age a.

Every combination of a life table and a rate of increase implies a determinate age composition, with an associated birth rate and death rate. We have followed Euler's implicit suggestion, and calculated a total of more than 5,000 stable populations, associated with the 200 model life tables (25 for each sex in each of the four "regional" families). We have exceeded his suggestion to calculate the reciprocal of the birth rate, and have printed many parameters of each stable population, including the proportion in each five-year interval, the cumulated proportion to ages at five-year intervals, and the birth rate, death rate, and rate of increase. Accompanying each stable age distribution is an age distribution of the deaths that would occur in the stable population.

The development of a fully articulated theory of stable populations was the work of Alfred J. Lotka. In 1907, he wrote a brief note[17] in which he stated equation (1) exactly as given here, and little different from an equation employed by Euler 150 years earlier of which Lotka was apparently unaware. In this article, Lotka showed that the relations inherent in a stable population were closely matched in the population of England and Wales in 1871–1880. Four years later, in a joint paper with F. R. Sharpe, Lotka first outlined the mathematical proof that the continuation of a specified fertility and mortality schedule would lead to an unchanging age distribution, which Sharpe and Lotka labeled "stable."[18] In a stable population, the rate of increase that comes to prevail is the sole real root of equation (2):

$$\int_0^{\omega} e^{-ra}p(a)m(a)\,da = 1 \tag{2}$$

where $m(a)$ is the proportion of persons of one sex who annually become parents of a child of the same sex, and ω is the highest age attained. Usually, $m(a)$ expresses the age schedule according to which women bear female babies, although it is equally appropriate for males.

In a series of more than 30 articles and a book, Lotka elaborated the theory of stable populations. He stated a method for calculating the one real root and the principal complex roots of equation (2), and showed how these values of r (real and complex) illuminate the approach to stability and the nature of the

---

[13] From the view point of computation, as is explained below, this parameter is the expectation of life at age 10.

[14] A detailed discussion of the construction of these tables appears in Chapter 2.

[15] Leonard Euler, "Recherches générales sur la mortalité et la multiplication du genre humain," *Histoire de l'Académie Royale des Sciences et Belles-Lettres,* 1760, pp. 144–64.

[16] Lotka used the term *Malthusian* to describe a population with a constant rate of increase and an unchanging mortality schedule, and the term *stable* for the special case of a Malthusian population when the constant rate of increase results from the prolonged prevalence of an unchanging fertility schedule.

ultimate stable population. He discovered and stated a large number of interrelationships among parameters in the stable populations; he illustrated the use of stable population concepts to promote a better understanding of what fertility and mortality schedules imply, specifically noting that the *intrinsic* (stable) rate of increase in the United States of 1920 was well below the then current (crude) rate of natural increase; he used stable population concepts to estimate the average size of family in Colonial America; he showed how the establishment of a stable population from the progeny of a single population element could be derived by considering births by *generations* rather than on an annual basis; and he analyzed the incidence of orphanhood, the extinction of families, and the growth of two species competing for a common food supply. The most systematic exposition of his contributions is in *Théorie analytique des associations biologiques* (Hermann et Cie, Paris, 1939). This book also contains a bibliography listing Lotka's principal contributions prior to 1939.

Since Lotka's death in 1949, there has been a revival of interest in stable population analysis, partly because the stable age distribution is often closely approximated under the demographic conditions found in many underdeveloped areas—a history of approximately constant fertility and steadily falling mortality. Such age distributions have been designated *quasi-stable.*[19]

CHAPTER 2

Calculation of Model Tables

A. CALCULATION OF FOUR FAMILIES OF MODEL LIFE TABLES

The four families of life tables presented in this volume are the result of a search for several distinctive patterns in the variation of mortality rates with age. The search originated in the impossibility of finding an acceptable one-parameter representation of all reliable mortality experience.

The various conventional functions (l_x, L_x, e_x°, etc.) of a life table can be constructed from a small number of life table death rates—${}_nq_x$'s. For example, knowledge of (${}_1q_0$, ${}_4q_1$, ${}_5q_5$, ${}_5q_{10}, \ldots,$ ${}_5q_{75}$) permits the calculation of l_x (and L_x) to age 80. The value of e_{80}° can be estimated from ${}_5q_{75}$ and T_{80}, calculated as $l_{80} \times e_{80}^\circ$, and life expectancy at the various ages can then be calculated. Thus, every life table can be considered a point in Euclidean space of 17 dimensions, where each coordinate axis represents the proportion dying in a particular age interval. A one-parameter set of model life tables is, then, a singly connected sequence of such points—a "line" that is as close as possible to the observed life tables. The United Nations model tables form a "line" that is derived by estimating a quadratic relation between the ${}_nq_x$ values in progressively older age groups; other model tables have been calculated from the data used by the United Nations using a straight line in the space whose coordinates are log q_x's.[1] The factor analytic approach[2] assumes that model tables can best be represented (at least for some purposes) as lying in an ellipsoid having more than one, but fewer than 17 dimensions. In the construction of model life tables by factor analysis, three parameters are considered adequate for a close representation of male and female life tables. The first parameter (closely correlated with e_0°) by itself defines a line passing close to the observed life tables; the other two can be viewed as specifying commonly observed age patterns of deviations from the principal line.

The representation of model life tables by means of the so-called logit transformation introduced by W. Brass is an alternative way of representing a set of life tables as being contained in a two-dimensional plane. In fact, the logit system can be viewed as consisting of two transformations: of age-specific rates into a survival function, and second, the transformation of the survival function to logit values. Suppose that $p(a)$ and $q(a)$ are the proportions surviving to age a and dying before age a, respectively, according to a given age-specific mortality schedule. Suppose further that $p_s(a)$ and $q_s(a)$ are proportions surviving and proportions dying according to a "standard" schedule. Logit $p(a) = \frac{1}{2} \log(p(a)/q(a))$, by definition. It is assumed that the mortality experience of at least some subset of all mortality experience can be encompassed in the relationship: logit $p(a) = \alpha + \beta$ logit $p_s(a)$. This equation defines a plane in the 17-dimen-

sion space for the logit of survival values to 17 ages, a plane spanned by a line from the origin through logit $p_s(a)$ and a line through the origin making an equal angle with all of the axes. Actually, since β differs only slightly from one, the locus of life tables generated in this way lies close to the line from the origin through the points representing the logit of $p_s(a)$. This system for generating model life tables has the advantage of permitting variation in two parameters for each "family" of tables considered, but the set of tables covered is nevertheless determined by the choice of a "standard" life table. The logit transformation can closely approximate all members of any one of the four families of the regional tables presented in this book by assigning a given table (for instance, that with a life expectancy of 30 years) as the standard, and by a suitable choice of α and β for the other tables in the family. However, it is not possible to give a close approximation of a life table in one family as a logit transformation of a standard table in another family.

The model tables presented here are based on a tendency that we noted for the life tables based on accurate data to cluster around four different lines, representing distinct age patterns of mortality in certain geographical regions.

The four families of life tables were isolated as the result of working with a preliminary one-parameter family of model tables designed to represent the entire collection of 326 life tables. The following method was used to construct the preliminary model tables: all of the q_x values were ordered, from highest to lowest, at each age. The values then were plotted as a function of order for each age, and occasional erratic fluctuations removed by hand smoothing. Preliminary model tables then were formed by putting together mortality rates with the same rank.

This system of construction has the virtue of simplicity, and of symmetrical treatment of mortality rates at all ages. That is, no particular rate or rates are singled out as the basis for estimating others. The usefulness of the preliminary set of tables is questionable, however, because the 326 tables are so widely scattered about the "line" that these model tables formed, as we could see by examining the two-dimensional scatter diagrams.

The next step was to examine deviations of individual life tables from the age pattern of mortality in the preliminary model tables. The pattern of deviations was measured by the difference between q_x in the given table and q_x in a model life table (with the same general level of mortality). The "comparison" model table was selected by first noting the expectation of life at birth in the model life tables with the same ${}_nq_x$ as the given life table, at $x = 0, 1, 5, \ldots, 75$. The median model table (the table with the median e_0°) was the "comparison" table. The graph showing ${}_nq_x - ({}_nq_x)_{\text{model}}$ displays, for ready visual comprehension, the age pattern of mortality relative to the age pattern in the model tables, in a way that does not depend on the overall level of mortality. Graphs of this sort were constructed for all 326 life tables. The following general observations emerged from an examination of the patterns:

1. Some life tables have large variations from the model patterns. Large deviations were especially frequent under age 10 and over age 60.
2. The biggest deviations were found in life tables where the quality of the underlying data is suspect: life tables for Western Europe prior to 1850; certain Eastern European life tables—for Russia in 1897 and 1926, for Bulgaria and Greece; and life tables in underdeveloped countries in Asia, Africa, and Latin America. In most of these tables, age reporting in the censuses, and doubtless in the mortality register, is inaccurate. The completeness of death registration—especially for infants—is uncertain.
3. When data are known to be accurate, deviations are usually moderate. Statistics that are comparatively free of age misstatement and omission are found in some European countries since 1870, in 20th century Canada, the United States, Australia, and New Zealand. Unfortunately, these areas have a rather narrow range of cultural diversity and doubtless represent a narrow sample of age patterns of mortality. It is of special interest to note, then, that the life tables of Taiwan and the more recent Japanese life tables—both based on accurate data—conform as well as do European tables to the preliminary model tables.

Two features of the deviations found within life tables based on accurate data led to the construction of four separate families of model tables: (a) the fact that the pattern of deviations is often similar among life tables expressing the mortality of the same population at different times, and (b) the fact that several groups of geographically linked populations exhibited similar patterns of deviations.

Figure 1 shows patterns of deviation in certain Scandinavian life tables; in tables from Germany, Austria, Czechoslovakia, Poland, and North Italy; and in tables from South Italy, Spain, and Portugal. Within each group the similarity of deviations is easily visible, although from group to group the patterns differ.

On the basis of an examination of the patterns of deviations in the 326 life tables for each sex, correla-

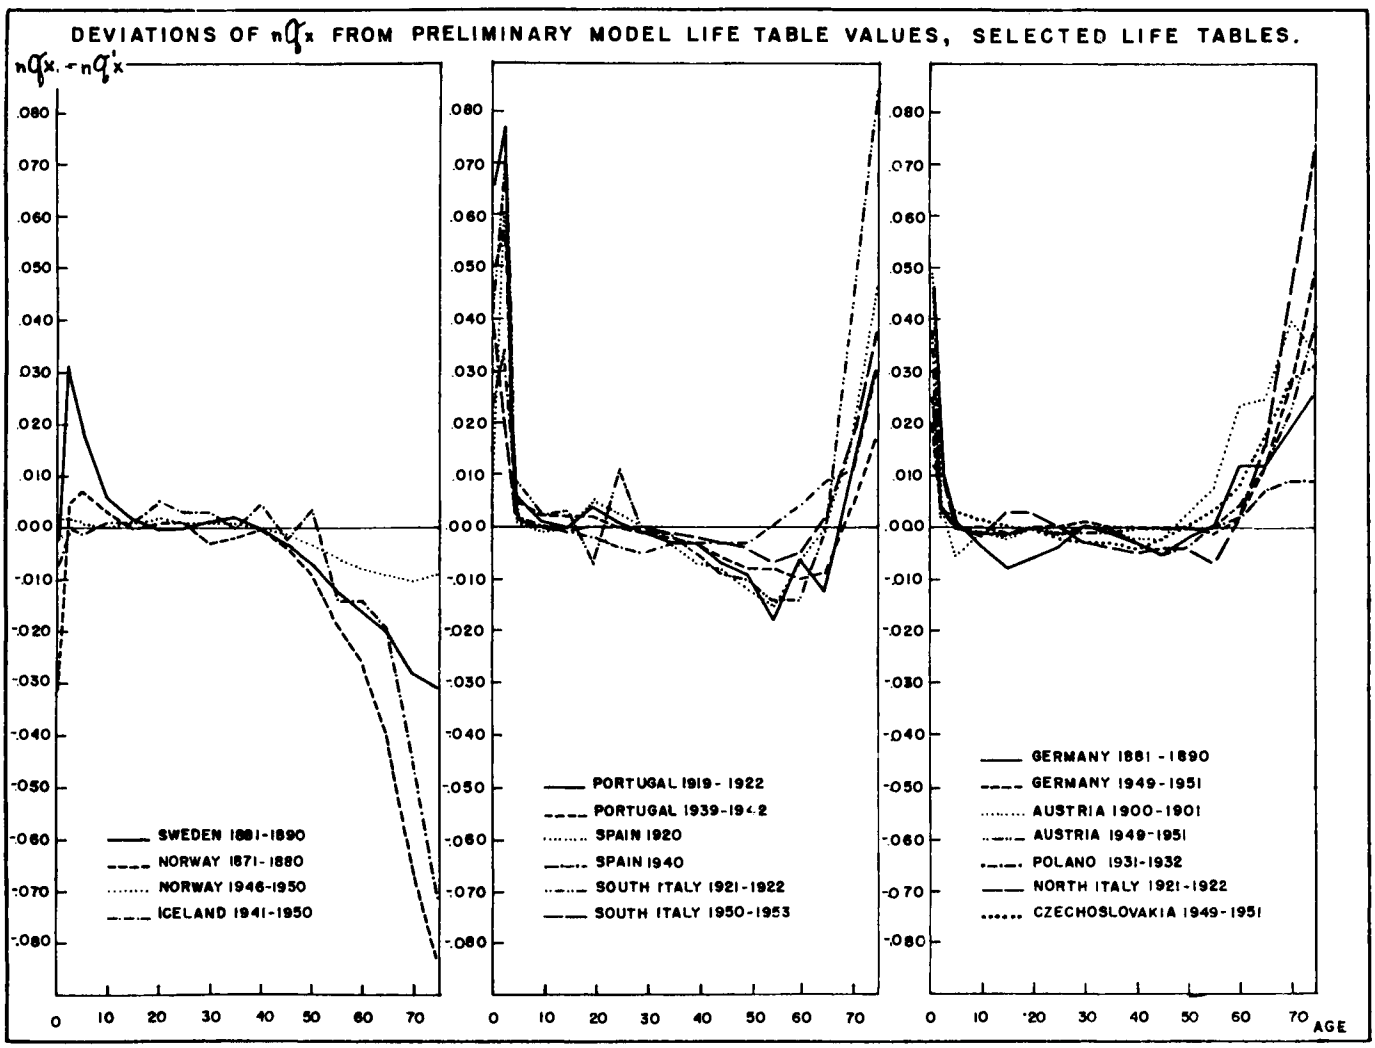

FIGURE 1. Deviations of mortality rates in three regional collections of life tables (${}_nq_x$) from mortality rates in a preliminary model life table (${}_nq'_x$). Selected tables for females.

tion matrices were calculated for various groups of life tables—zero-order correlations among 19 variables: log ${}_nq_x$ at various ages (x = 0, 1, 5, 10,..., 75), and expectation of life at age 0 and age 10. We experimented with nine principal sets of correlations for each sex: (1) tables before 1870; (2) tables for Russia and certain Balkan areas; (3) tables for selected Central European areas; (4) tables for Scandinavian countries; (5) tables for Spain, Portugal, and Southern Italy; (6) tables for Switzerland; (7) tables for countries with reliable data not included in (3), (4), (5), or (6); (8) tables reflecting mortality when there is an unusually high incidence of tuberculosis; and (9) modern tables based on relatively inaccurate data—primarily from Asia, Africa, and Latin America.

The nature of the life tables underlying each of the "regional" model tables is as follows:

1. Tables underlying "East" model tables. The life tables of Austria, Germany (including tables in 1878 and the 1890s for Bavaria and Prussia), Czechoslovakia, North and Central Italy, Hungary, and Poland show deviations from the preliminary model life tables characterized by high mortality rates in infancy, and increasingly high rates over age 50 (Figure 1, right panel). Switzerland's life tables show deviations very similar to this group until 1920, although the early Swiss life tables have a less conspicuous positive deviation in infancy. After 1920, the Swiss life tables show zero or negative deviations in infant mortality. Hungarian life tables exhibit substantial deviations in an age pattern, indicating an extraordinary incidence of tuberculosis. Inclusion of the Hungarian life tables lowers the correlation coefficients from age 5 to 35, but has little other effect, and they were

omitted from the calculation of the "East" model tables, as were the Swiss life tables. The tables in the "East" group include 13 from Germany (of which 3 are from Prussia or Bavaria), 5 from Austria, 3 from Poland, 4 from Czechoslovakia, and 6 from North or Central Italy.

2. Tables underlying "North" model tables. The life tables of Norway, Sweden until 1920, and Iceland deviate from the preliminary model tables in having low infant mortality rates, and rates that are lower than the model rates by an increasing margin at ages beyond 45 or 50. Later Swedish life tables do not have this characteristic pattern (Figure 1, left panel). In the life tables of all three "North" countries from 1890 or 1900 to 1940, there are deviations in the mortality rates from age 5 to 35 or 40, indicating the effect of an unusual incidence of tuberculosis. Model tables incorporating this experience would be suitable only for populations with a high endemicity of tuberculosis. Consequently, the "North" model tables are based on Swedish mortality from 1851 to 1890 (four tables), Norwegian mortality from 1856 to 1880 and from 1946 to 1955 (four tables), and the Iceland life table for 1941–1950.

3. Tables underlying "South" model tables. The life tables of Spain, Portugal, and Southern Italy have high mortality under age 5, low mortality from about age 40–60, and high mortality over age 65, relative to the preliminary model tables (Figure 1, center panel). Early tables—prior to 1912—for all Italy had these same characteristics. The "South" model life tables were based on 5 tables for all Italy (1876–1910), 8 tables for Portugal (1919–1958), 1 table for Sicily (1951), 3 for South Italy (1921–1957), and 5 for Spain (1900–1940).

4. Tables underlying "West" model life tables. The "West" model life tables were based on mortality experience recorded in populations known to have relatively good vital statistics, and not showing a persistent systematic pattern of deviations from the preliminary model tables. In other words, the tables underlying the "West" models are a residual collection after the "East," "South," and "North" tables have been removed. (The Swiss tables were also omitted, having a recent pattern resembling the "West" up to age 45 or 50, and the "East" above age 50.) The tables underlying the "West" models include 7 from Australia (1881–1955), 4 from Belgium (1880–1949), 7 from Canada (1926–1959), 11 from Denmark (1895–1955), 11 from England and Wales (1871–1959), 1 from Estonia (1933), 4 from Finland[3] (1881–1955), 16 from France (1871–1959), 5 from Ireland (1925–1952), 3 from Israel (1949–1959), 6 from Japan[4] (1949–1960), 1 from Latvia (1936), 1 from Luxemburg (1947), 10 from the Netherlands (1870–1955), 12 from New Zealand (1906–1959), 2 from Northern Ireland (1925–1959), 7 from Scotland (1891–1959), 5 from Sweden (1931–1959), 3 from Taiwan[5] (1921–1959), 4 from the Union of South Africa white population (1920–1947), and 10 from the United States (1901–1958). Tables before 1870 were eliminated because most of those examined (from France, the Netherlands, and England and Wales) had irregular patterns that appeared to arise from faulty data.

[3] Finnish tables from 1890 to 1940 were omitted because of a strongly tubercular age pattern of mortality.

CORRELATION MATRICES OF MORTALITY RATES

Intercorrelations among log ${}_1q_0$, log ${}_4q_1$, log ${}_5q_x$ (x ranging from 5 to 75), and e_0° and e_{10}° are shown in Tables II–IX for the data underlying the "West," "North," "East," and "South" model life tables, females and males. Table X compares the correlations between e_{10}° and log ${}_nq_x$ in "West," "North," "East," and "South" life tables, with the correlations in pre-1870 European life tables, in Russia and the Balkans, and in life tables from Asia, Africa, and Latin America.

It is evident in these tables that the grouping of areas having similar age patterns of mortality (as evidenced in similar deviations from the preliminary model tables) produces very high correlations. The highest correlations are in the "North," "East," and "South" tables; the "West" group—a residual collection characterized by nonsystematic deviations from the preliminary model tables—is not characterized by a distinctive pattern, and has somewhat lower correlation coefficients among mortality rates by age.

A conspicuous feature of these intercorrelations is that with few exceptions (mostly in the "East" group) the intercorrelations are lower among male than among female mortality rates. The biggest differences are in the "West" correlations, especially in comparisons of male and female correlations between mortality rates for ages over 50 on the one hand, and under 30 on the other. The principal cause of the lower correlation among male mortality rates is that the pattern of male mortality has changed with the

[4] Japanese tables prior to 1949 have a strongly tubercular age pattern of mortality.

[5] Taiwanese life tables before 1921 were omitted because of an especially deficient registration of births and infant deaths in earlier years. (George W. Barclay, *Colonial Development and Population in Taiwan*, Princeton University Press, Princeton, N.J., 1954, pp. 159ff.)

passage of time—notably in a tendency in recent life tables toward higher death rates above age 50 relative to the rates under 30.[6]

[6] We have calculated multiple correlations with each mortality rate as a dependent variable, and time (date of the life table) as an additional independent variable. The multiple correlation coefficients for males typically exceed the corresponding zero order correlation by a wide margin, and the difference for females is typically trivial. Thus, zero-order and multiple correlation between log ${}_5q_{65}$ and $-e_{10}^{\circ}$ are about the same (.952). Among "West" males, the corresponding correlations are: multiple R = .932 and zero-order r = .887. In consequence, the female model life tables are more closely representative of mortality experience in the areas from which the data are drawn than are the male model life tables.

CONSTRUCTION OF FOUR SETS OF MODEL LIFE TABLES

The principal steps in the calculation of the four sets of model life tables were as follows:

1. Intercorrelation matrices for ${}_nq_x$ and $\log_{10}({}_nq_x)$ were calculated for the "North," "South," "East," and "West" data. [e_0° and e_{10}° were left untransformed (no logarithms taken) in the second sets of intercorrelations.]

2. Least-square linear regressions of ${}_nq_x$ and of log ${}_nq_x$ on e_{10}° were fitted for both sexes in all four "regions." The regression coefficients are given in Table XI.

TABLE XI. Regression coefficients relating ${}_nq_x$ and $\log_{10}(10{,}000\ {}_nq_x)$ to e_{10}° for regional model life tables, male and female (coefficients A_x and B_x in ${}_nq_x = A_x + B_x\, e_{10}^\circ$; and A_x' and B_x' in $\log_{10}(10{,}000\ {}_nq_x) = A_x' + B_x'\, e_{10}^\circ$)

3. The values of ${}_nq_x$ estimated from the logarithmic regression are always above those from the regression of untransformed mortality rates at the high and low extremes of observed life expectancies, and the logarithmic regression values are always lower in the middle range. In other words, the two regression lines always intersect twice within the range of observations. In constructing the model life tables, ${}_nq_x$ values were taken from the simple regression at all points to the left (i.e., at points with lower life expectancy) of the first intersection of the regression lines; and to the right of the second intersection, ${}_nq_x$ values were taken from the logarithmic regression. Between the two intersections, the mean of the ${}_nq_x$ values from the two regressions was used.

4. From various values of the independent variable (e_{10}°), ${}_nq_x$'s at ages 0, 1, 5, 10,..., 75 were calculated. From each such set of ${}_nq_x$'s, $l_1, l_5, l_{10}, \ldots, l_{80}$ were computed, with l_0 taken as 100,000. Above age 80, l_x was calculated by the Gompertz formula

$$l_x = l_{80} \exp[-(\mu(80)/k)(e^{k(x-80)} - 1)]$$

where

$$k = \log(\mu(105) - \mu(77.5))/27.5,$$
$$\mu(105) = .551 + 1.75({}_5q_{75}) \quad \text{(males)}$$
$$\text{and} \quad .613 + 1.75({}_5q_{75}) \quad \text{(females)},$$
$$\mu(77.5) = (l_{75} - l_{80})/{}_5L_{75}$$

5. ${}_nL_x$ and e_x° were estimated by the use of the following formula:

$${}_1L_0 = k_0 l_0 + (1 - k_0) l_1$$
$${}_4L_1 = k_1 l_1 + (4 - k_1) l_5$$
$${}_5L_x = k_x(l_x) + (5 - k_x) l_{x+5}, \qquad x = 5, 10, \ldots, 75$$

${}_5L_x$ (x = 80, 85, 90, and 95) was calculated by numerical approximation of the integral $\int_x^{x+5} l(y)\,dy$, using the Gompertz expression for $l(y)$ at intervals of one-fifth of a year. T_{100} was calculated as $\int_{100}^{\infty} l(x)\,dx$:

$$T_x = \sum_x^{95} {}_5L_y + T_{100}$$
$$e_x^{\circ} = T_x / l_x$$

The values of k_0 were as follows, when ${}_1q_0 \geq 0.100$:

	For females	For males
West, North, South "Regions"	0.35	0.33
East "Region"	0.31	0.29

The values of k_0, ${}_1q_0 < 0.100$, were given by the following expressions:

	For females	For males
"West," "North," "South"	$k_0 = 0.050 + 3.00\,{}_1q_0$	$k_0 = 0.0425 + 2.875\,{}_1q_0$
"East"	$k_0 = 0.010 + 3.00\,{}_1q_0$	$k_0 = 0.0025 + 2.875\,{}_1q_0$

The values of k_1 were as follows, when ${}_1q_0 \geq 0.100$:

	"West"	"North"	"East"	"South"
For females	1.361	1.570	1.324	1.239
For males	1.352	1.558	1.313	1.240

The values of k_1, ${}_1q_0 < 0.100$, were given by the following expressions:

	For females	For males
"West"	$1.524 - 1.625\,{}_1q_0$	$1.653 - 3.013\,{}_1q_0$
"North"	$1.733 - 1.627\,{}_1q_0$	$1.859 - 3.013\,{}_1q_0$
"East"	$1.402 - 1.627\,{}_1q_0$	$1.541 - 3.013\,{}_1q_0$
"South"	$1.487 - 1.627\,{}_1q_0$	$1.614 - 3.013\,{}_1q_0$

$$k_5 = 2.25$$
$$k_x = 2.6, \qquad x = 10, 15, \ldots, 70$$
$$k_{75} = 2.5$$

6. Age-specific mortality rates (${}_nm_x$) were calculated from the formula ${}_nm_x = {}_nd_x / {}_nL_x$, where ${}_nd_x = l_x - l_{x+n}$.

7. Five-year survival rates for projecting five-year age groups (${}_5P_x$) were calculated by the formula ${}_5P_x = {}_5L_{x+5} / {}_5L_x$, x = 0, 5,..., 95.

The first survival rate is the proportion surviving to the end of a five-year time interval of persons born during the interval, estimated as ${}_5L_0/5l_0$. The last survival rate is of persons over 95 at the beginning of an interval (and over 100 at the end), estimated as T_{100}/T_{95}.

8. Both male and female tables are calculated by regression of ${}_nq_x$ on e_{10}°. The values of e_{10}° that were used as the independent variable in constructing the female tables were chosen by an iterative procedure, so as to give even 2.5-year intervals of e_0° from 20 to 80 years. The values of e_{10}° for males were chosen so as to correspond with the female e_{10}°'s in a way that preserves the typical relation of e_{10}° for males and females at each level of mortality within each family of life tables. The relationship posited was as follows:

$$(e_{10}^{\circ})_m - (\overline{e_{10}^{\circ}})_m = \frac{\sigma_m}{\sigma_f}[(e_{10}^{\circ})_f - (\overline{e_{10}^{\circ}})_f]$$

where σ_m and σ_f are the standard deviations of expectation of life at age 10 for males and females. This expression is the equation for the straight line with a slope intermediate between the regression of $(e_{10}^{\circ})_m$ on $(e_{10}^{\circ})_f$, and the inverse of the regression of $(e_{10}^{\circ})_f$ on $(e_{10}^{\circ})_m$. The correlation between e_{10}° for the two sexes is more than .99 in all instances, so that the two regression lines are almost identical.

9. Single year values of l_x for ages between 1 and 5 were determined after l_x at ages 1, 5, 10,..., 100 had been calculated by the methods already described. These values are given in Table XIV at end of

Chapter 3. The method of calculation was to determine weights (α_2, α_3, and α_4) so that l_i could be estimated as $\alpha_i l_1 + (1 - \alpha_i) l_5$. Constant values of α_i were used when ${}_1q_0 \geq 0.100$, as follows:

	Females			Males		
	α_2	α_3	α_4	α_2	α_3	α_4
"West"	.489	.260	.112	.484	.258	.110
"North"	.589	.336	.145	.584	.331	.143
"East"	.473	.249	.102	.466	.244	.103
"South"	.457	.207	.075	.458	.208	.074

For low levels of infant mortality (${}_1q_0 < 0.100$) variable weights, α_i' were used, of the form $\alpha_i' = \alpha_i + \beta_i (0.100 - {}_1q_0)$. The values of β_i were as follows:

	β_2	β_3	β_4
For females	0.656	0.601	0.370
For males	1.353	1.089	0.571

THE USE OF TWO REGRESSIONS IN CALCULATING ${}_nq_x$ IN MODEL TABLES

There are two considerations that make questionable the use of regression equations in constructing model life tables:

1. A regression of a particular functional form (linear, quadratic, logarithmic, etc.) often fits the data better over some parts of the range of observations than others, and often represents the data poorly at extremes, and may in particular provide an implausible extension or extrapolation of relationships beyond the range of observations.
2. "Least-squares" regression equations of any given functional form establish two relations between any pair of variables, as each is considered the independent variable, and the other dependent.

In an estimation of one variable from a known value of another, the use of one variable as dependent and the other as independent is clearly appropriate and there is a logical reason for employing one regression rather than the other. But there is no logical basis for selecting one mortality rate or another as independent when trying to estimate a set of interrelationships among mortality rates at different ages. In the original United Nations model life tables, the selection of ${}_1q_0$ as the sole purely independent variable, and the calculation of a chain of regressions, with each mortality rate first being a dependent and then an independent variable, created a tendency (because of the well-known "regression toward the mean") to incorporate less of the observed range of variability at higher ages than at lower ages. A regression chain starting at the highest ages and ending with ${}_1q_0$ would have been equally plausible, and would have produced somewhat different model tables.

The use of two linear regressions (logarithmic and nonlogarithmic) and the selection of e_{10}° as the index of mortality (the independent variable in calculating mortality rates for every age group) result in a procedure that lacks elegance, but takes account of the considerations stated in the preceding paragraph.

The expectation of life at age 10 is an approximate general index of the level of mortality, an index that is not strongly dependent on the mortality rates for any one age group. (In contrast, e_0° is strongly influenced by the value of ${}_1q_0$.) Correlations with e_{10}° are near to unity at most ages in all "regions." The choice of e_{10}° as the basis for regression estimates is not an arbitrary fixing of any one mortality rate in the resultant model life tables. All mortality rates are separately subject to "regression toward the mean." Hence, if an e_{10}° two standard deviations above the mean is chosen as the basis for estimating a model life table, *all* of the mortality rates will be somewhat less than two standard deviations below their mean value; but the sequence of mortality rates is not ever more compressed toward the mean as age advances.

One final oddity: the e_{10}° in a given model life table (calculated from T_{10}/l_{10}) is not the same as the e_{10}° that served as the basis for estimating the various mortality rates in the given table. There are two e_{10}°'s associated with each model life table: the e_{10}° that served as the index by which all ${}_nq_x$'s were estimated, and the e_{10}° implied by the ${}_nq_x$'s themselves. The relationship between the calculated e_{10}° and ${}_nq_x$ (for any x) is curvilinear, even over the range where estimation by linear regression of ${}_nq_x$ on e_{10}° is employed. The line representing the relation between the calculated e_{10}° in the model life table and ${}_nq_x$ for each x fits the observed ${}_nq_x$'s better than the regression line.

The facts that led us to combine estimates from regressions of ${}_nq_x$ and log ${}_nq_x$ on e_{10}° were as follows:

1. The two sets of correlation coefficients were comparable in magnitude. There were 48 instances where the nonlogarithmic correlation exceeded the logarithmic by at least .003; 55 where the logarithmic coefficients were larger by this margin; and 33 instances where the difference was less than .003 (Table XII). However, there is a different relative effect on the two kinds of correlation coefficients of "scatter" in mortality rates at high levels of mortality on the one hand, and low levels of mortality on the other. At low levels of e_{10}°, the associated mortality rates usually have large arithmetic deviations one from another,

TABLE XII. Correlation coefficients (times 1,000) between $(-e_{10}^{\circ})$ and ${}_nq_x$ and between $(-e_{10}^{\circ})$ and log ${}_nq_x$ in life tables underlying model life tables "West," "North," "East," and "South"

but not especially large logarithmic deviations, since the latter depend on the ratios of mortality rates one to another. Hence, the "scatter" found among high mortality rates depresses the nonlogarithmic correlation coefficient, but not the logarithmic. Conversely, the logarithmic correlation coefficient is depressed by the large relative differences that may accompany small arithmetic differences among low mortality rates. In short, the relative size of the nonlogarithmic and logarithmic correlations may be more a reflection of the special geometry among high and among low mortality rates than an indication of whether the underlying relationship is linear or exponential. In fact, the position of the logarithmic regression line is affected more than that of the nonlogarithmic line by the geometry of the cluster of observations at lower mortality levels, and the position of the nonlogarithmic regression line is affected more than that of the logarithmic by the scatter of observations at higher mortality levels.

2. The logarithmic regression line at the highest observed expectations of life is closer to the observations, and represents a more plausible extension of the observations, than the nonlogarithmic regression line. This closer fit is caused partly by the sensitivity of the logarithmic regression to relative rather than absolute deviations, and partly by the fact that declining linear exponential functions are necessarily asymptotic to zero, and never give negative values. In contrast, the nonlogarithmic regression line falls *below* the observed mortality rates for the higher values of e_{10}°, and sometimes indicates negative mortality estimates near the upper limits of observed values of e_{10}° —a patent absurdity.

3. At the other end—high mortality, low expectation of life—of the range of observed values, the nonlogarithmic regression line is usually closer to empirical mortality rates, and, in this range, also represents a more plausible extension of observed relations. The exponential necessarily becomes steeper at lower expectations of life, and would yield absurdly high estimated mortality rates if e_{10}° were assumed to have a low value.

Through the middle range—between the two intersections of the lines—sometimes one line is closer, and sometimes the other to the observed mortality rates. To have a uniform rule, and minimize discontinuity in the sequence of model tables, we estimated mortality rates from the nonlogarithmic regression up to the first intersection, used the mean of the two regression estimates between the two intersections, and used the estimates from the logarithmic regression at expectations of life at age 10 above—to the right of—the second intersection.

ESTIMATION OF LIFE TABLE VALUES OTHER THAN ${}_nq_x$

The weights (k_0 and k_1, the "separation factors") that relate ${}_1L_0$ to l_0 and l_1, and ${}_4L_1$ to l_1 and l_5, can be shown

to equal the age at death of those members of the life table population who die under age 1 (for k_0), and the age at death minus 1 of those who die between ages 1 and 4 (for k_1). The values of the factor k_0 were therefore determined by examining the average age at death under 1 year in the records of the populations whose mortality experience was the basis for the four regional model life tables. No consistent variation in average age of infant deaths was found at infant mortality levels above 0.100, nor any consistent differences among the "regions," except that k_0 for "East" infants was consistently less than in the other "regions," and k_0 for males was generally slightly less than for females. When ${}_1q_0$ is very low—in the range from 0.015 to 0.100—there is a clearly apparent tendency for k_0 to vary, because at very low levels of infant mortality infant deaths are much more concentrated immediately after birth. This tendency was represented by allowing k_0 to rise linearly from a typical level at the lowest observed infant mortalities until at ${}_1q_0 = 0.100$ it reaches the plateau typical of higher infant mortality.

The value of k_1 in the expression ${}_4L_1 = k_1 l_1 + (4 - k_1)l_5$ was determined from the estimates of l_2, l_3, and l_4 given in Table XIV at the end of Chapter 3. In fact ${}_4L_1$ was calculated on the assumption that l_x can be considered linear in each single-year age interval from 1 to 5; thus, $k_1 = 0.5 + \alpha_2 + \alpha_3 + \alpha_4$, when $l_2 = \alpha_2 l_1 + (1 - \alpha_2)l_5$, etc. Each α_i was based on the relation of l_i to l_1 and l_5 observed in the life tables upon which each family of model tables was based. As with k_0, it was noted that when ${}_1q_0 > 0.100$, the values of each α_i showed no tendency to vary as a function of the level of mortality, although at levels of mortality below ${}_1q_0 = 0.100$ there is a tendency for the deaths from age 1 to age 5 to be more evenly distributed, and for l_x in this range to be more nearly linear. Hence, at low levels of mortality, each α_i was allowed to fall as ${}_1q_0$ increases in a manner analogous to the rise in k_0. The values of α_2, α_3, and α_4 are somewhat different in each region. It is reassuring to note that when ${}_1q_0 > 0.100$, the α_i's observed in the life tables underlying each regional set of model tables clustered about an average typical of the set, and differing from the average value of α_i for the other "regions." In other words, each region has a distinctive pattern of mortality from 1 to 5, as well as at other ages.

The values of k_x from $x = 5$ to 75 make a rough allowance for the typical distribution of deaths within five-year age intervals. It can be shown that k_x is the average number of person-years lived in the interval by those who die in the interval. In the first edition, these values were all taken to be 2.5 years.

The extension of the model life tables to age 100 has been accomplished by an adaptation of the Gompertz function, according to which age-specific mortality rates at older ages increase exponentially with rising age; that is, $\mu(x) = \mu(a)e^{k(x-a)}$, where a is any age within the Gompertz region—above age 55 or 60. We have examined death rates by single years of age at advanced ages in a number of populations with virtually complete registration of deaths, and very accurate reporting of age. The suitability of the Gompertz function as an expression of the general shape of old age mortality is confirmed by the close approximation to a straight line of the logarithm of single-year mortality rates in such populations.

To construct new model life tables above age 80, it was necessary to estimate the death rate at age 80 [$\mu(80)$] and the annual rate of increase (k) in death rates with age above 80, since it is readily shown, when mortality rates increase exponentially with age [when $\mu(x) = \mu(a)e^{k(x-a)}$ for x greater than a] that

$$l_x = l_a \exp[-(\mu(a)/k)(e^{k(x-a)} - 1)]$$

The life table functions up to age 80—including l_{80} and ${}_5q_{75}$—are calculated by the steps described above. Age-specific mortality rates [the "force of mortality," $\mu(x)$] are then assumed to rise exponentially to a very high value at age 105.

The death rate at age 105 [$\mu(105)$] is estimated from ${}_5q_{75}$ by the simple estimator $\mu(105) = .551 + 1.75\,{}_5q_{75}$ (males) and $.613 + 1.75\,{}_5q_{75}$ (females). This formula produces estimates of $\mu(105)$ in the "West" model tables that decline steadily for females from 1.785 (when $e_0^\circ = 20$) to 1.014 (when $e_0^\circ = 80$). (A death rate of over 1.0 may appear to be a numerical absurdity, but a rate of 1.785 means 1.785 deaths per person-year, but only about 0.15 deaths per person-month.) Life tables with high mortality at ages 75–80 thus maintain higher mortality to age 105 than life tables with low mortality at 75–80, but the rate of increase in mortality rates with age is less for the life tables with high mortality at 75–80. The rate of increase (k) in mortality rises in the "West" female tables from 0.0794 when $e_0^\circ = 20$ to 0.1082 when $e_0^\circ = 80$. The higher rate of increase of mortality rates with age when mortality at 75–80 is low implies that death rates in the low-mortality life tables ultimately overtake the rates in the high-mortality tables. The result is that for females the age-specific death rate would reach about the same very high level—about 8.9 deaths per person year—at age 125.3, and for males a still higher common level (about 10 deaths per person year) at about age 128.3. Even with a radix of trillions at age 100 there would be no survivors to such a high age.

The validity of the life table values above age 80

calculated by these procedures has been tested by comparing e°_{80} in 56 life tables for each sex from countries possessing exceptionally good data on old age mortality with the e°_{80} in model life tables in which ${}_5q_{75}$ is the same. The life tables were from Belgium, Czechoslovakia, Denmark, England and Wales, Finland, France, Germany, the Netherlands, Norway, Sweden, Switzerland, Australia, New Zealand, Taiwan, and Japan—countries known to have virtually complete registration of deaths, and minimal misstatement of age. In these 56 life tables, e°_{80} ranges from 4.41 to 7.38 years for females, and from 4.01 to 6.20 years for males. The e°_{80} in the model life table with the same ${}_5q_{75}$ differed by less than 0.2 year from the e°_{80} in the national life table in more than 75% of the comparisons, and the correlation between actual e°_{80} and model life table e°_{80} was 0.98 for females and 0.96 for males.

THE VALUE OF FOUR FAMILIES OF MODEL LIFE TABLES

The separate families of model life tables provide estimates that in our judgment are quite reliable when utilized judiciously for populations within the areas upon which each family of model tables is based. This point is illustrated by Figure 2 in which the mortality rates in the highest and lowest mortality tables (for females) in each group are compared with the mortality rates in the model table with the same expectation of life at birth. Figure 3 shows how the four female model tables differ at various levels of e°_{0}. The closeness of fit encourages us to believe that the "East" family of age patterns of mortality provides a better basis for estimating life tables in, for example, Poland or North Italy than would one of the other families, or a single collection of life tables such as the United Nations' models. We also feel (with less conviction) that the extrapolated model life tables approximate the different patterns of mortality that likely prevailed or will prevail at life expectancies below or above the range of observed experience within the regions covered.

A part of our motivation in constructing these families of model life tables was to provide a research tool that promised to be useful in studying historical population changes in Europe. At the time the model

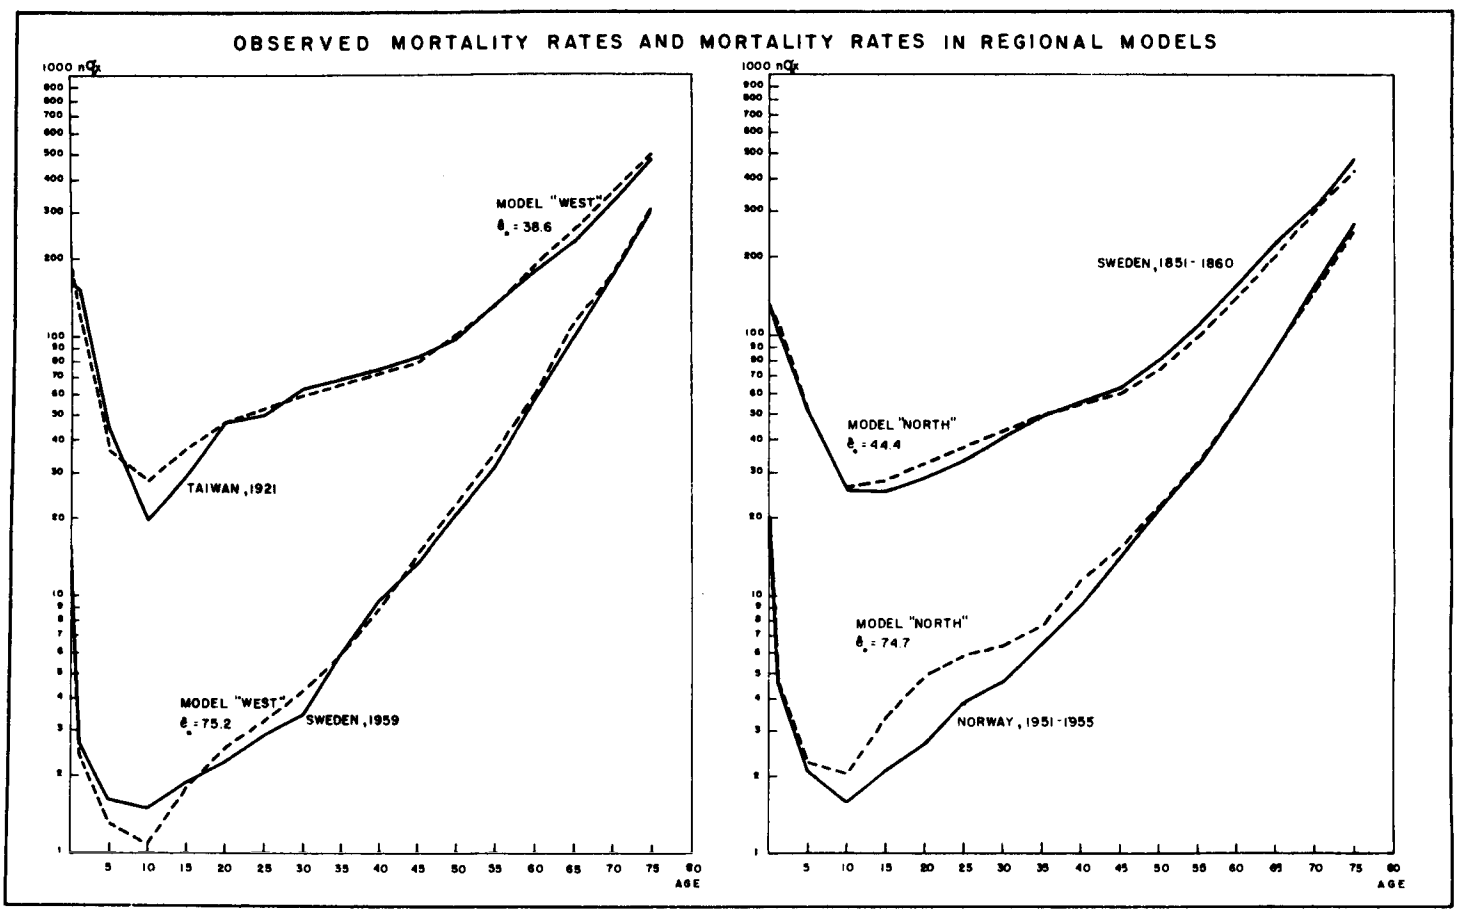

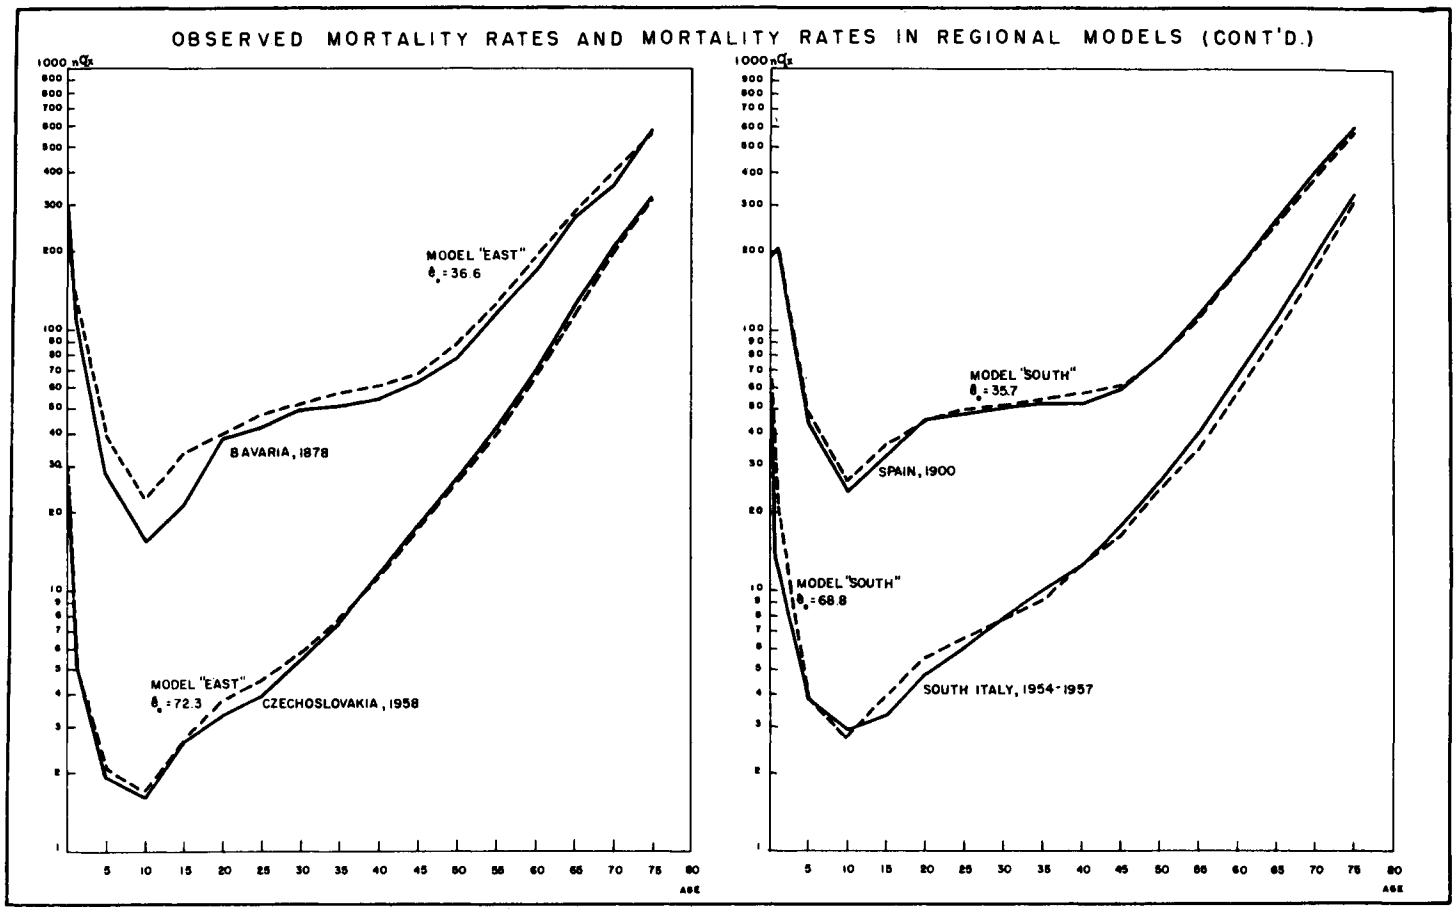

FIGURE 2. Values of ${}_nq_x$ in female life tables with highest and lowest e°_{0} among life tables in the collections underlying the four families of model life tables compared with values of ${}_nq_x$ in life tables with the same e°_{0} of the corresponding model.

tables were first constructed, the Office of Population Research was embarked on a province-by-province study of the long-term decline of fertility in Europe. The model tables have proved to be very valuable in various forms of estimation for this project, and in studies of historical demography by many others.

The four families of model tables also provide a basis for estimating life tables in populations outside the ones that underlie the model tables themselves. We would suggest utilizing the "West" family in the usual circumstances of underdeveloped countries where there is no reliable guide to the age pattern of mortality that prevails. The other families can be moderately useful in these circumstances to illustrate the variability in estimates that arises from assuming well-established age patterns of mortality other than the pattern underlying the "West" tables. We must concede that this use of the four families is far from satisfactory, because there is no strong reason for supposing that the age patterns of mortality exhibited in these four families covers anything like the full range of variability in age patterns in populations under different circumstances. At the same time, we feel that the age patterns of mortality exhibited in life tables from underdeveloped areas are usually quite untrustworthy because of defects in the underlying data. The question of what is the pattern of mortality in a population of an underdeveloped area is essentially unresolvable, because there exists no way to determine exactly the age of an illiterate person who does not know it himself, and *a fortiori* of a deceased person who did not know his own age at the time of death. By the time a population has reached the stage where age-specific mortality rates can be measured with confidence, the level and age pattern of mortality may have changed, so that the pattern of mortality during the underdeveloped period may never be known.

B. CALCULATION OF FOUR FAMILIES OF STABLE POPULATIONS

Each of the more than 5,000 stable age distributions is a combination of a model life table and a rate of increase, as in equation (1), Chapter 1. The proportions of persons in 22 age intervals have been calculated, the intervals being under 1, 1–5, 5–10,..., 95–100,

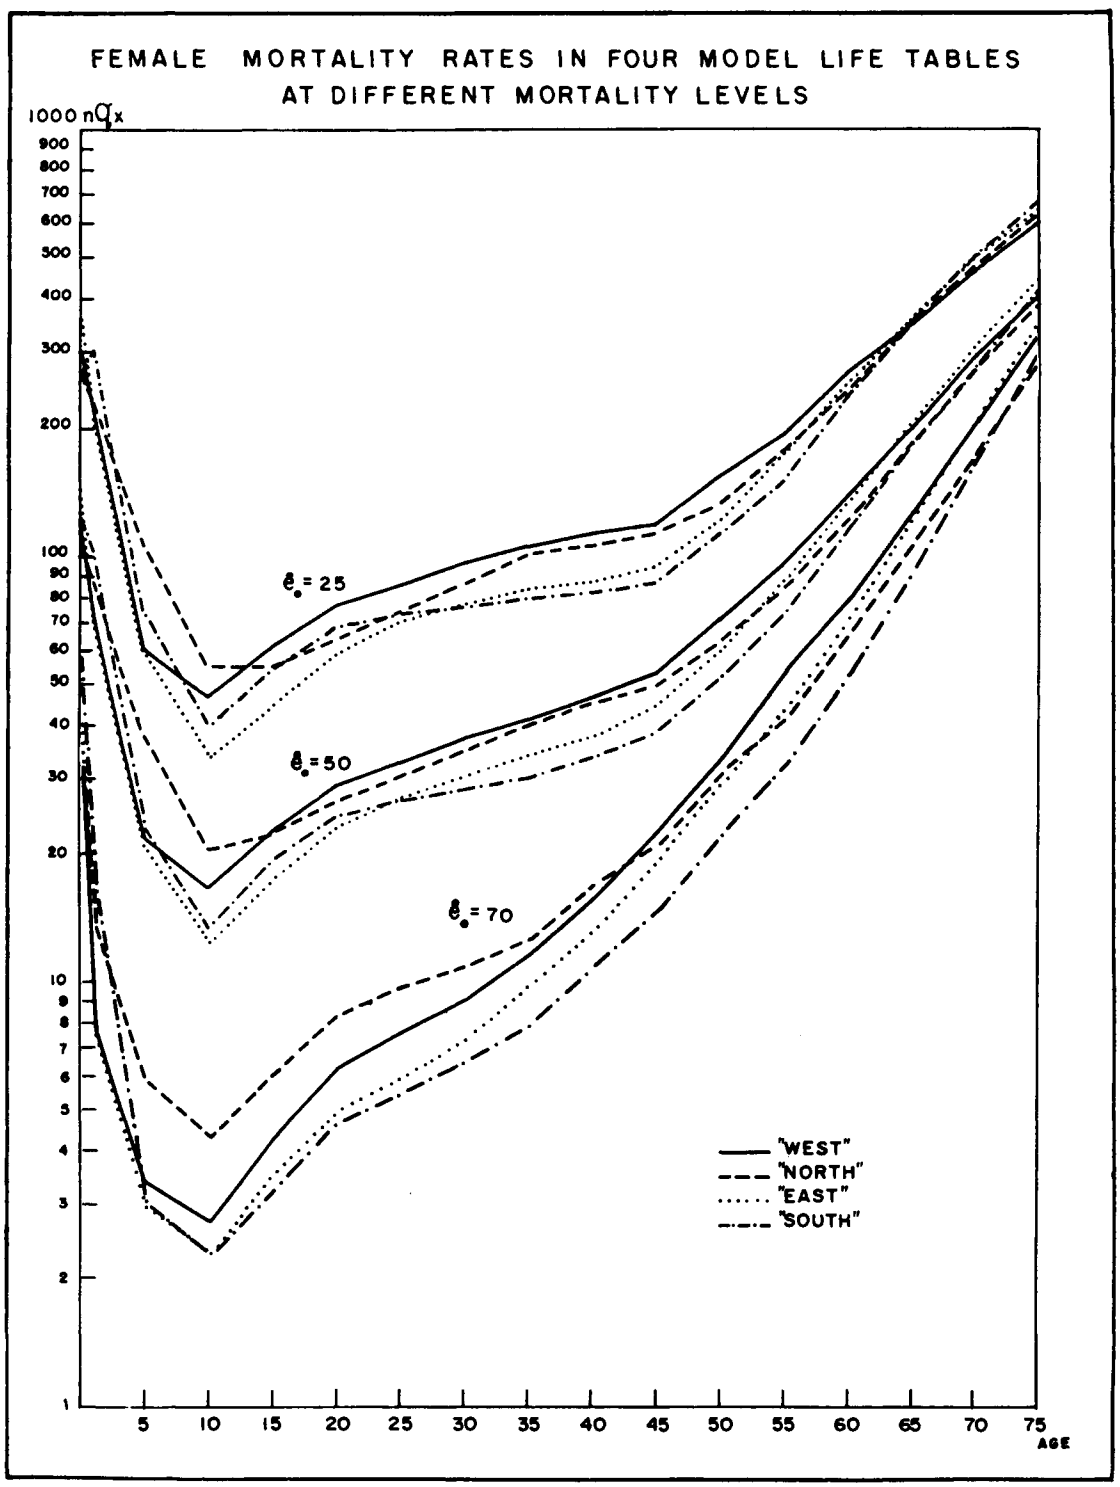

FIGURE 3. Values of ${}_nq_x$ in the four families of model life tables ("West," "North," "East," and "South") when e_0° = 25, 50, and 70 years, for females.

100+. The exact expression for the proportions in each interval is

$$\int_{a_1}^{a_2} c(a)\,da = b\int_{a_1}^{a_2} e^{-ra}p(a)\,da \qquad (3)$$

and

$$b = \left[\int_0^{\omega} e^{-ra}p(a)\,da\right]^{-1} \qquad (4)$$

In our calculations, the following approximation was employed:

$$\int_{a_1}^{a_2} e^{-ra}p(a)\,da \doteq e^{-r\bar{a}}\int_{a_1}^{a_2} p(a)\,da \qquad (5)$$

This approximate formula is exactly accurate if the appropriate interior value of $\bar{a}$ is used. For every interval up to age 80, $\bar{a}$ was taken as $(a_1 + a_2)/2$ and $\int_{a_1}^{a_2} p(a)\,da$ was taken from the L_x column. Above 80, the integral was evaluated by fractions of a year of age from the Gompertz expression for $p(a)$. This refinement is needed because the assumption that $\bar{a}$ is $(a_1 + a_2)/2$ leads to imprecise results when the product of r and ${}_5m_x$ has values in the order of 1% or more.

An important characteristic of the stable population is the underlying *fertility schedule.* Although a fertility schedule and a mortality schedule fully determine the intrinsic rate of increase, there is a *family* of fertility schedules that, in conjunction with a given mortality table, would produce the same intrinsic rate of increase, and hence the same stable population. The relationship between fertility and the intrinsic rate of increase is given in equation (2), Chapter 1.

Lotka calculates r from given fertility and mortality schedules by deriving a power series with coefficients that are the cumulants of the net fertility function, $\phi(a) = p(a)m(a)$:

$$\mu_1 r - \mu_2\frac{r^2}{2!} + \mu_3\frac{r^2}{3!} + \cdots - \log R_0 = 0 \qquad (6)$$

where $R_0 = \int_0^{\omega} p(a)m(a)\,da$ (the net reproduction rate), μ_1 is the mean of $\phi(a)$, and μ_i is the ith cumulant of $\phi(a)$. In Lotka's calculation of r, terms above $(\mu_2/2)r^2$ are neglected, implying that moments of $\phi(a)$, or of $m(a)$, higher than the second have little effect on the relation between fertility and the intrinsic rate of increase. This is an empirical property of the age schedules of human female fertility. The form of fertility schedules has only limited variability. In all populations where reliable records have been kept, fertility is zero until about age 15, rises smoothly to a single peak, and falls smoothly to zero by age 45–50. The mean age of the fertility schedule is usually between about 26 and 33 years.

Variations in the form of the age schedule of fertility occur because of different customs governing age of cohabitation, the use of contraception or abortion, etc. But in all schedules the higher moments about the mean are not large enough to affect r, and there is such a nearly constant relationship of the variance to the mean that knowledge of the gross reproduction rate (the area under the maternity schedule) and the mean age of the schedule is sufficient to estimate r with a very small margin of error.

Although variations in the higher moments of the fertility schedule are not important in determining r, the mean age of the fertility schedule has a strong influence on the rate of increase, especially when fertility is high.[8] For example, with the same mortality schedule ("West" females, $e_0^{\circ} = 50$ years), a GRR (the gross reproduction rate) of 3.500 connotes an r of 0.0394 when $\bar{m} = 27$ years, and of only 0.0307 when $\bar{m} = 33$ years. Thus, each stable population is consistent with different GRR's for fertility schedules with different mean ages. It can be shown that $b \doteq \text{GRR}\,c(\bar{m})$, where $c(\bar{m})$ is the proportion of the female population at the mean age of the fertility schedule.[9] If two stable populations have the same age distribution, but different $\bar{m}$'s, their GRRs are related by the approximate equation

$$\text{GRR}_1/\text{GRR}_2 = c(\bar{m}_2)/c(\bar{m}_1)$$

but

$$c(\bar{m}_2)/c(\bar{m}_1) \doteq \exp[(\bar{m}_1 - \bar{m}_2)(r + \mu(\bar{a}))]$$

where $\mu(\bar{a})$ is the death rate at the midpoint of the interval between the two mean ages. We have tabulated GRR for $\bar{m} = 29$ years; to determine GRR for a fertility schedule with any other mean age, the following equation should be employed:

$$\text{GRR}(\bar{m}) = \text{GRR}(29)\exp[(\bar{m} - 29)(r + \mu(\bar{a}))] \qquad (7)$$

where $\mu(\bar{a})$ is the death rate at $\bar{a} = (29 + \bar{m})/2$; $\mu(\bar{a})$ is estimated by linear interpolation between $\mu(27.5)$ (approximated by ${}_5m_{25}$) and $\mu(22.5)$ or $\mu(32.5)$.

In the "growth rate" set of tables, the values of r were given $(-0.010, -0.005, \ldots, +0.050)$; calculation was needed to find GRR for $\bar{m} = 29$ years. This calculation was made by evaluating the integral in the following equation:

$$\text{GRR}(29) = \left[\int_0^{\omega} e^{-ra}m'(a)p(a)\,da\right]^{-1} \qquad (8)$$

---

[9] A. J. Coale. *The Growth and Structure of Human Populations. A Mathematical Investigation,* Princeton University Press, Princeton, N.J., 1972, p. 43.

where $m'(a)$ is a maternity function with $\bar{m} = 29$, and GRR = 1.0; [$m'(a)$ has the following annual numbers of female births per woman in age intervals from 15–19 to 45–49: 0.018, 0.042, 0.056, 0.044, 0.028, 0.010, 0.002]. Equation (8) follows from the fact that

$$K \int_0^{\omega} e^{-ra} p(a) m'(a)\, da = 1 \qquad (9)$$

where K is the scalar multiple relating the fertility schedule with the GRR in question to $m'(a)$, which by definition has a GRR of 1.000.

In the "GRR" tables, the "given" quantity is the gross reproduction rate, where $\bar{m} = 29$ years. It was necessary to calculate the r implied by this given fertility schedule and the relevant mortality schedule. r was calculated by a recursive method. An estimated value (r') was substituted in the integral in equation (2), Chapter 1, and a second (more accurate) estimate (r'') derived from the divergence of the integral from unity.[10] Iteration was employed until the integral in equation (2) differed from unity by less than one part in a billion.

The death rate was taken as the difference between b [equation (4)] and r.

The average age of each population was calculated as the sum of the proportion of the population within each age interval multiplied by the mean age of persons in the interval. The mean age of the interval from a to $a + n$ was taken as $a + (n/2) - (n^2/12)(r + m)$, where m is the mortality rate at the interval. The average age at death was calculated by summing the proportion of deaths in each age interval multiplied by the mean age at death of those dying in the interval, with a correction of $-nr^2/12$ for intervals of width n. The mean age at death of those dying in the interval is k_0 for deaths under age 1, $1 + k_1$ for deaths to persons aged 1–5, and $x + k_x$ for x from ages 5 to 75. Above age 80 the mean age of the population and the mean age at death in each interval was calculated from the Gompertz expression for l_x at intervals of one-fifth of a year.

[10] A. J. Coale, "A New Method of estimating Lotka's r," *Population Studies* (London), Vol. 2, No. 1 (July 1957), pp. 92–94.

The first approximation was obtained by the formula $r' = (\log R_0)/(\mu_1 - 0.7 \log R_0)$, which is based on these considerations: (a) $r = (\log R_0)/T$; (b) $T = \mu_1 - \frac{1}{2}\mu_2 r + \cdots$; and (c) $\mu_2/2\mu_1 = 0.7$ for human fertility schedules. This value of r' is so close to r that the integral in equation (2) usually equals 1.000 ± 0.00001.

CHAPTER 3

Uses of the Tables[1]

A. MODEL STABLE POPULATIONS

TABULATION OF STABLE POPULATIONS

The large number of parameters tabulated for each stable population, and the large number of age distributions included in this volume are designed to make the tables as widely useful as possible, given the limitations inherent in the data upon which they are based.

The scheme of tabulation is designed with two considerations in mind: (a) to provide stable age distributions for the full range of mortality and fertility levels likely to be relevant either in fitting the tables to observed data, or in analyzing the hypothetical consequences of fertility and mortality schedules; and (b) to tabulate values at small enough intervals so that linear interpolation is sufficiently exact.

There are two overlapping sets of stable population tables giving information that is to a large extent duplicated. Each set of tables includes age distributions of population (and also age distributions of deaths) for every model life table. In the first set of tables (the "growth rate," or "r," tables) the basic index of variation for a given mortality schedule is the rate of increase r; and in the second set (the "GRR" tables), the index of variation is the gross reproduction rate. In the first set, stable age distributions with intrinsic rates of natural increase from -0.010 to $+0.050$ are provided, at intervals of 0.005 in r. The variation in GRR ($\bar{m} = 29$ years) in these tables is from 2.38 to 12.15 when $e_0^\circ = 20$ years, and from 0.75 to 4.06 when $e_0^\circ = 80$ years ("West" mortality). Combinations of very rapid growth and high mortality are clearly impossible, because of the impossible level of fertility implied. Age distributions with GRR's above 4.0 or 5.0 will not be used very often, except for illustration.

The second set of tables provides age distributions for every life table with gross reproduction rates (when $\bar{m} = 29$ years) that vary from 0.800 to 6.000 in increments that become larger at higher levels of fertility. The growth rates implied vary from -0.0473 to 0.0233 when $e_0^\circ = 20$ years, and from -0.0079 to .0648 when $e_0^\circ = 80$ years ("West" mortality). The distributions representing combinations of very low fertility and high mortality and of very high fertility and low mortality will doubtless be used very rarely.

The two sets of tables cover slightly different universes of fertility–mortality combinations. The user should note that at high levels of mortality (short expectation of life) the "growth rate" set includes higher

[1] Since the first edition of these tables was published, a rather extensive literature on the use of model life tables and stable populations has appeared. Among the most important items are:

1. United Nations, *Manual IV: Methods of Estimating Basic Demographic Measures from Incomplete Data*, Population Studies No. 42, New York, 1967.
2. United Nations, *The Concept of a Stable Population: Application to the Study of Populations of Countries with Incomplete Demographic Statistics*, Population Studies No. 39, New York, 1968.
3. Norman Carrier and John Hobcraft, *Demographic Estimation for Developing Societies*, Population Investigation Committee, London School of Economics, London, 1971.
4. U. S. National Academy of Sciences Committee on Population and Demography, *Demographic Estimations: A Manual on Indirect Techniques* (to be published).

fertility levels, and the "GRR" set covers lower fertility levels. At the other end of the mortality scale (low mortality, long life expectation) the two sets start at about the same low fertility boundary, but the "GRR" set extends to higher fertility levels. The purpose of providing two sets of tables is to make analysis and interpolation more convenient. The user will find the "growth rate" set of tables more convenient in exploring the implications (for example) of different recorded intercensal rates of increase, and the "GRR" set more convenient in analyzing the effects of different levels of fertility.

MULTIPLE INTERPOLATION IN THE STABLE AGE DISTRIBUTION TABLES

In using these tables, it is essential to recall that each stable age distribution is the consequence of a mortality schedule and a growth rate, that there are a variety of parameters (birth rate, death rate, mean age) that are implied by each distribution, and that all that is implied about fertility in any age distribution is that the schedule must be one of many possibilities having an appropriate combination of GRR and $\bar{m}$.

In the universe of stable age distributions associated with any one of the four families of model life tables, it is possible to locate a unique stable population from knowledge of two nonredundant parameters, such as the birth rate and e_0°, the rate of increase and e_0°, the proportion under 20 and the rate of increase, or the average age and the death rate. However, it must be borne in mind that measures of total fertility (such as the GRR) do not constitute in themselves an adequate parameter in identifying a unique stable population, but must be supplemented by the mean age of the fertility schedule, and by some other variable as well.

An appropriate stable age distribution can be located by a process of interpolation (more than one is usually required), which is illustrated in the following examples:

Example 1. What is the proportion under 30 in the male stable age distribution with "West" mortality, $e_0^\circ = 21.60$ years, $r = 0.0112$?

First, find by linear interpolation in the "growth rate" set of "West" model age distributions that at mortality level 2 ($e_0^\circ = 20.444$ for males[2] the proportion under 30 is $(0.24)(0.7349) + (0.76)(0.7033) = 0.7109$ when $r = 0.0112$, and at level 3 ($e_0^\circ = 22.852$ for males) the proportion under 30 is $(0.24)(0.71(5) + (0.76)(0.6886) = 0.6965$ when $r = 0.0112$. Then, interpolating between these two values, we find that the proportion under 30 is $(0.520)(0.7109) + (0.480)(0.6965) = 0.7040$ when e_0° is 21.60. This process has located a stable age distribution that lies (horizontally) between columns headed "10.0" and "15.0" and (vertically) between pages headed "mortality level 2" and "mortality level 3." By other interpolations of this sort, other parameters of this stable population can be found. Thus, the birth rate of the stable age distribution in question is 60.76 per thousand, the death rate 49.56, the mean age 22.18 years, etc.

Example 2. What is the female intrinsic birth rate, death rate, and rate of increase in a population with a GRR of 1.695, $\bar{m} = 26.432$, and $e_0^\circ = 73.4$ years (females from the United States, 1962)?

From the formula given in equation (7), Chapter 2,

$$\text{GRR}(26.432) = \text{GRR}(29)\exp[(26.432 - 29.0)(r + \mu(\bar{a}))]$$

where $\bar{a}$ is $(26.432 + 29.0)/2 = 27.72$. When $e_0^\circ = 72.5$ ("West" female, level 22.0), $\mu(27.5) = .00104$, and $\mu(32.5) = 0.00129$; hence, $\mu(27.7) = .00105$. For GRR(29) = 1.75, at this level of mortality $r = 18.06$ per thousand; for GRR(29) = 2.00, $r = 22.83$. Utilizing these values of r and $\mu(\bar{a})$, one finds that GRR(26.432) is $1.75\exp[-(2.57)(0.01911)] = 1.666$ in the stable population with $r = 18.06$, and $2.00\exp[-2.57(.02388)] = 1.881$ in the stable population with $r = 22.83$. When GRR(26.432) is 1.695, it is found, by interpolation, that $r = 18.70$ per thousand, and $b = 25.94$. A parallel calculation when $e_0^\circ = 75.0$ gives $b = 25.76$ and $r = 19.26$. By a final interpolation (for $e_0^\circ = 73.4$ years), b and r are found to be 25.88 and 18.90 per thousand, respectively.

ANALYTICAL USES OF THE STABLE AGE DISTRIBUTIONS

These extensive tables of stable populations can be used to illustrate relationships among demographic variables, since the stable population shows the ultimate implications of a fertility and a mortality schedule. For example, a comparison of the intrinsic rates of births, deaths, and natural increase for females from the United States in 1962 (25.88, 6.98, and 18.90 per thousand, as calculated above) with the corresponding *observed* values for the female population

[2] The expectation of life at birth is indicated directly on the first set of age distributions as Pop. size/births = 1, for $r = 0$, because of the well-known fact that in a stationary population, expectation of life at birth is the reciprocal of the birth rate.

TABLE XIII. Selected parameters of "West" female stable populations for different expectations of life at birth, and gross reproduction rates (mean age of fertility schedule 29 years)

	Gross reproduction rate ($\bar{m}$ = 29)					
e_0°	.80	1.00	1.50	2.00	3.00	4.00
	Proportion under age 15					
20	.098	.128	.196	.255	.349	.418
30	.116	.151	.228	.293	.391	.462
40	.129	.166	.250	.318	.419	.489
50	.137	.177	.265	.336	.438	.509
60	.145	.187	.278	.350	.453	.524
70	.149	.192	.286	.359	.463	.534
80	.141	.185	.281	.357	.464	.536
	Proportion at ages 65 and over					
20	.165	.134	.085	.058	.032	.020
30	.178	.142	.087	.055	.031	.019
40	.189	.149	.090	.059	.030	.018
50	.198	.154	.091	.060	.030	.017
60	.201	.156	.092	.059	.029	.017
70	.212	.165	.096	.061	.030	.017
80	.259	.202	.119	.075	.036	.021
	Mean age (years)					
20	44.5	41.5	35.7	31.6	26.2	22.7
30	43.8	40.5	34.2	29.9	24.4	21.0
40	43.5	39.9	33.2	28.8	23.3	20.0
50	43.3	39.5	32.6	28.1	22.5	19.3
60	43.1	39.1	32.0	27.5	21.9	18.7
70	43.3	39.2	31.9	27.2	21.6	18.4
80	45.6	41.1	33.0	27.9	21.9	18.6
	Birth rate (per thousand)					
20	9.6	13.3	22.6	31.5	47.7	61.4
30	9.7	13.4	22.5	31.0	45.9	58.1
40	9.7	13.4	22.3	30.5	44.5	55.9
50	9.7	13.3	22.1	30.0	43.4	54.2
60	9.7	13.3	21.9	29.7	42.6	52.9
70	9.6	13.1	21.7	29.3	41.9	51.8
80	8.9	12.4	20.9	28.5	41.1	51.0
	Death rate (per thousand)					
20	56.9	53.1	48.7	47.7	49.5	52.9
30	43.7	39.8	35.0	33.5	33.9	35.7
40	34.9	30.9	25.8	23.9	23.4	24.3
50	28.4	24.4	19.1	16.9	15.7	15.9
60	23.4	19.3	13.9	11.4	9.7	9.3
70	19.4	15.3	9.7	7.1	5.0	4.4
80	16.8	12.6	7.0	4.4	2.3	1.5

(21.54, 8.07, and 13.47 per thousand)[3] shows that the age structure of the female American population caused a lower birth rate and higher death rate than would the age distribution implied by the fertility and mortality schedules themselves. This comparison (of crude and intrinsic rates) was much emphasized in the 1920s and 1930s when the crude rate of increase in Western countries was well *above* the intrinsic rate.

Table XIII shows that the interplay of mortality, fertility, and age composition can be illustrated by numbers extracted from the model stable populations. Note, for example, the small effect of mortality and the large effect of fertility on the mean age of the population, and the existence of a minimum death rate with each life table—a minimum that occurs at a GRR between 2.00 and 2.50 when $e_0^\circ = 20$, between 2.500 and 3.00 when $e_0^\circ = 30$, between 3.00 and 4.00 when $e_0^\circ = 50$, and above 4.00 when $e_0^\circ = 70$ years.[4]

USE OF THE STABLE AGE DISTRIBUTIONS TO ESTIMATE DEMOGRAPHIC PARAMETERS IN POPULATIONS WITH HISTORIES OF CONSTANT FERTILITY AND CONSTANT OR GRADUALLY CHANGING MORTALITY

The immediate purpose of calculating the preliminary version of these tables several years ago in the Office of Population Research was to estimate birth rates, death rates, and approximate age distributions in research on populations for which there were only incomplete or inaccurate data. Euler proposed estimation by methods such as these in the article cited earlier. In 1907, Lotka noticed how closely the stable age distribution implied by the life table and rate of natural increase of England and Wales fitted the actual age distribution; and since World War II there has been a revival of interest in the stable population because of evidence that age distributions in the so-called underdeveloped areas are not very different from stable age distributions. Various techniques have been employed to select or calculate a stable age distribution best fitting the data available. Once a stable age distribution has been selected, its characteristics can be assumed to approximate those of the population in question.

Three examples illustrate this use of the tables.

Example 1. Given the female age distribution for England and Wales in 1881, and the fact that e_0° was 44.62 in 1871–1880, estimate the birth rate for the years preceding the census, on the assumption that the age distribution approximates the stable.

The cumulative proportions of females in the 1881 census to age 5, 10, 15, 20, 25, and 30 are 0.1332, 0.2516, 0.3565, 0.4524, 0.5436, and 0.6236,

[4] These stable age distributions are used to illustrate various other interrelations in A. J. Coale, "Birth Rates, Death Rates, and Rates of Growth in Human Populations," in Mindel Sheps and J. C. Ridley (eds.), *Public Health and Population Change,* University of Pittsburgh Press, Pittsburgh, Pennsylvania, 1965, and in A. J. Coale, *The Growth and Structure of Human Populations. A Mathematical Investigation,* Princeton University Press, Princeton, N. J., 1972.

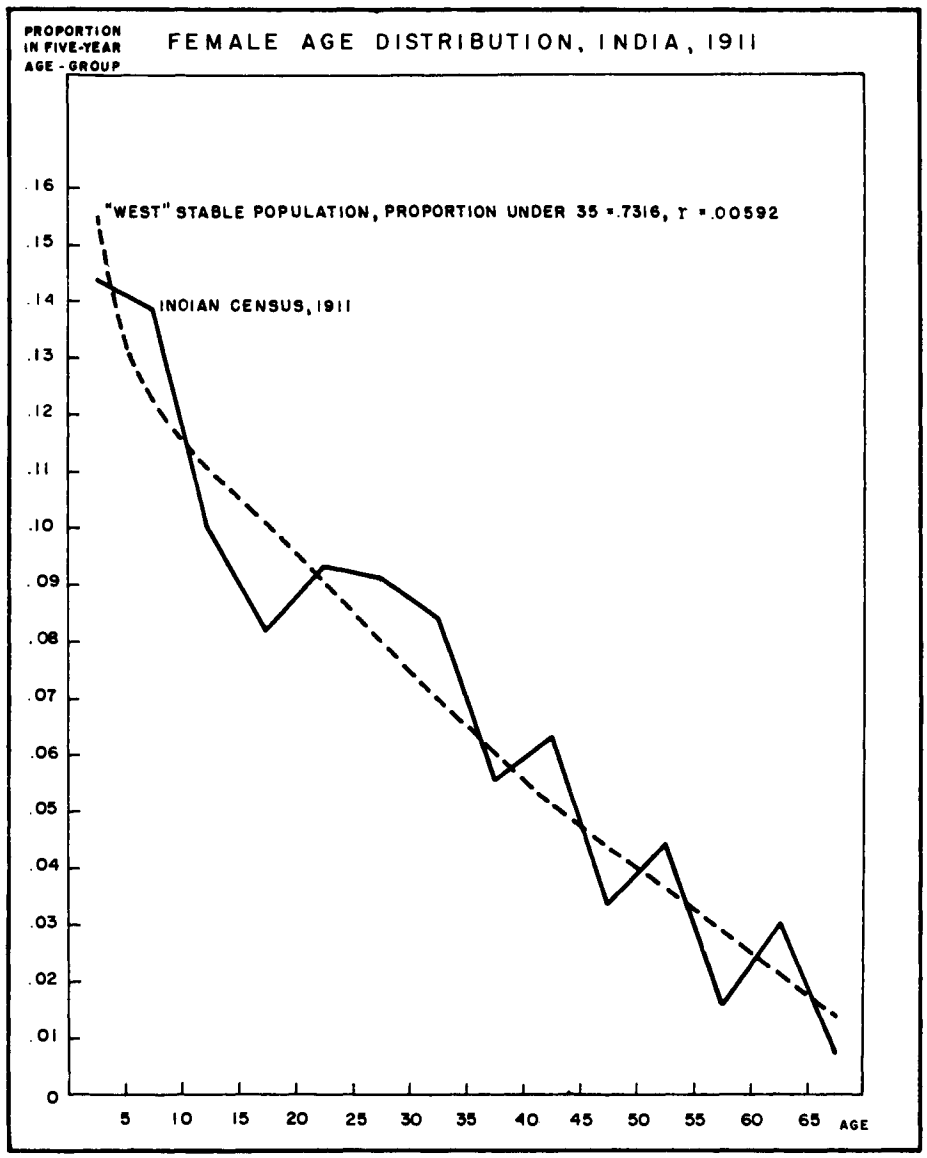

FIGURE 4. Female age distribution in India, 1911, as recorded in census, and approximated from "West" stable population with same proportion under age 35, and a growth rate of 0.0073.

respectively. These proportions are utilized with the given e_0° to locate, by interpolation, a sequence of female "West" stable populations having the following sequence of birth rates: 33.7, 34.2, 34.0, 34.1, 34.5, and 34.8 per 1,000.

For comparison, the female registered female birth rate in 1851–1860 was 32.65; in 1861–1870 33.5, and in 1871–1880 33.7. The rates adjusted for underregistration by Glass[5] for these periods are 34.0, 34.2, and 34.0.

Example 2. Estimate the birth rate, death rate, e_0°, and age distribution for India, 1911, from the reported age distribution, and the intercensal growth rate.

Age distributions in the Indian censuses are characterized by extreme age heaping and other indications of faulty data. In addition to the misreporting of ages, it is also likely that persons in some age intervals are subject to exceptional underenumeration. Hence, the birth rate and the expectation of life at birth estimated from the rate of increase and the proportion cumulated to age 5, 10,..., 35 are not nearly as consistent as in 19th century England and Wales.

Estimates of the female birth rates in India based

[5] D. V. Glass. "A Note on the Under-Registration of Births in Britain in the 19th Century," *Population Studies* (London), Vol. 5, No. 1 (July 1951), pp. 70–88.

on (a) the proportions 0–5, 0–10,..., 0–35, (b) the intercensal rate of increase 1901–1911, and (c) "West" model age distributions are 42.1, 50.3, 45.9, 40.3, 41.4, 44.7, and 49.1 per thousand.[6] The values of e_0° in these stable populations are 29.0, 24.1, 26.5, 30.4, 29.5, 27.2, and 24.7 years. These varying sequences of estimates reflect the conspicuous relative undercounts of ages 0–4, 10–14, and 15–19 that are seen in a comparison of the 'West" stable age distribution that has the same proportion under 35 as in the census, and the intercensal rate of increase (Figure 4). This example illustrates how wide is the range of uncertainty in making estimates based on censuses of illiterate populations. Moreover, there is an additional uncertainty as to whether the "West" pattern of mortality is appropriate. Estimates based on the proportion to age 35 and the intercensal rate of increase in "North," "East," and "South," model age distributions are 51.5, 62.2, and 60.1, respectively, per thousand for the birth rate (instead of 49.1 in the "West" distribution), and 23.0, 19.3, and 20.1, respectively, for e_0° (instead of 22.1). There is some reason for believing that the "West" stable is the most likely choice at such a high level of mortality. In spite of the obvious uncertainties, we feel that a minimum estimate of 49–51 for the birth rate, and a maximum estimate of 22–24 for e_0° is warranted.

The 1911 age distribution of India has been taken as an example rather than data from a more recent census because the 1921 age distribution was affected by the extraordinary influenza epidemic that began in 1918, and because post-World War I age distributions have been affected by declining mortality. Declining mortality changes the age distribution in a way that lowers the estimates of birth rates. If the decline is gradual, the effects may be ignored, and the resultant estimates can be useful, even if slightly biased. The effect of declining mortality has been discussed briefly in two recent articles[7] and is analyzed more fully in the manual that the Office of Population Research prepared for the United Nations.

Example 3. Estimate the birth rate for England and Wales for 1871–1880 from the age distribution of deaths and the rate of natural increase.

In a pioneering article on estimating vital rates by stable population analysis, Bourgeois-Pichat suggested using the age distribution of deaths[8] as a means of identifying a stable age distribution closely fitting the population in question. Even if the registration of deaths is incomplete, deaths as registered may be reasonably representative in their distribution by age of actual deaths, at least at ages above infancy. The age distribution of registered mortality provides a means independent of population censuses of selecting a stable age distribution. The proportions of the deaths over age 5 among females in England and Wales that occurred over age 30, 50, and 65 were 0.766, 0.552, and 0.357, respectively. Given the female rate of natural increase in 1871–1880 (0.0140, adjusted for underregistration of births), and interpolating in the tables showing the age distributions of deaths, the following estimates of the birth rate are obtained: 33.2, 33.8, and 33.4. Note how closely these rates compare with those derived in an earlier example.

B. USE OF MODEL LIFE TABLES, BY THEMSELVES, OR WITH MODEL STABLE POPULATIONS

The four families of model life tables are closely representative of age schedules of mortality in the "regions" upon which they are based, with these provisos:

1. Any extraordinary incidence of a cause of death that is highly age-and-sex specific produces a mortality schedule that naturally does not conform to the model tables. Examples are Norwegian mortality at the turn of the century, when tuberculosis was an extraordinary cause of death, populations affected by the influenza pandemic of 1918–1920, or populations experiencing heavy military casualties.
2. The most recent life tables in many countries have male mortality rates over age 45 or 50 higher than in the corresponding model tables.
3. Within the large residual "region"—the "West" —there are populations with more deviant mortality patterns than in populations in the other "regions."

Subject to these reservations, the model life tables may be used as substitutes for tables calculated by the

Coale, "Estimates of Various Demographic Measures through the Quasi-Stable Age Distributions," in *Emerging Techniques in Population Research*, proceedings of the 1962 Annual Conference of the Milbank Memorial Fund (New York 1963), pp. 175–193. See also Paul Demeny, "Estimation of Vital Rates for Populations in the Process of Destabilization," *Demography* (Chicago 1965) Vol. 2, pp. 516–530.

[8] Jean Bourgeois-Pichat, "Utilization de la notion de population stable pour mesurer la mortalité et la fécondité des populations des pays sous-développés," *Bulletin de l'Institut International de Statistique* Vol. 36, Part 2 (Stockholm 1958), pp. 94–121.

usual actuarial methods in applications involving populations within the "regions." This substitution is especially useful for standard demographic calculations, such as population projections.

The model life tables can be used in selecting an appropriate model stable population. Sometimes mortality estimates for only a restricted age range are available. William Brass had devised a way of estimating survival rates for children to age 1, 2, 3, and 5 from the proportion of children ever born reported as surviving by women 15–19, 20–24, etc.[9] The availability of these estimates makes it possible to select a model life table (in any of the four families, or in all four, to illustrate the resulting variations) on the basis of the value of l_1, l_2, l_3, l_4, and l_5 given in Table XIV at the end of this chapter, and if conditions warrant the assumption that the population has approximately stable characteristics, knowledge of only one additional parameter—say the proportion of the population under 20—would serve to fix the choice of a model age distribution.

C. GLOSSARY OF SYMBOLS USED IN TABLES

GENERAL REMARKS

The main body of this volume consists of photographic reproductions of computer tables. Limitations on printout formats explain some peculiarities of the notation. Readability and mnemonic convenience, rather than formal elegance, were sought in designating the various indices printed in the tables. A description of these designations is given below. First the symbol is shown as it is used in the tables, followed by the conventional notation, if any, in square brackets, and a brief explanation of the meaning of the symbol.

NOTATION IN MODEL LIFE TABLES

q(x)	$[{}_nq_x]$	Probability at age x of dying before reaching age $x + n$.
d(x)	$[{}_nd_x]$	Number of deaths between age x and $x + n$ out of an original cohort of 100,000.
m(x)	$[{}_nm_x]$	Death rate in the life table population (number of deaths per person-years lived) between age x and $x + n$.
l(x)	$[l_x]$	Number of survivors at age x out of an original cohort of 100,000.
L(x)	$[{}_nL_x]$	Number of person-years lived between age x and $x + n$ by an original cohort of 100,000. This column gives the age distribution in a stationary population with 100,000 annual births and deaths.
P(x)	$\left[\frac{{}_5L_{x+5}}{{}_5L_x}\right]$	The proportion of persons in a given five year age group in the stationary population alive five years later. Note however that the entry after age zero in this column in P(birth), $[{}_5L_0/5l_0]$; and that the entry after age 1 is P(0–4), $[{}_5L_5/{}_5L_0]$; and that the entry after age 95 is $T(100)/T(95)$, $[T_{100}/T_{95}]$.
T(x)	$[T_x]$	Number of person-years lived at age x and over by an original cohort of 100,000.
e(x)	$[e_x^\circ]$	Average number of years remaining to be lived (expectation of life) at age x.

In the first and last columns of the life tables the exact ages $x = 0, 1, 5, \ldots, 100$ are shown. Note that the width of age interval, denoted by the subscript n in the conventional notation is implicit in the sequence of these exact ages. Thus, the width of the first interval is one year (between exact age 0 and 1); the width of the second interval is four years (between exact age 1 and 5); and from then on the width of interval is five years up to age 100. The last line of the tables refers to the "open" age interval of exact age 100 and over, except for columns 1, P, T, and e, where the concept of interval is not applicable.

NOTATION IN MODEL STABLE POPULATIONS

(a) Symbols in Column Headings

r	Growth rate, that is, intrinsic rate of increase [r] for 1,000 persons of given sex.
GRR	Female gross reproduction rate with a mean of 29 years for the underlying maternity schedule.

(b) Symbols in Stubs

AGE	For the conventional age distributions population at age (x) and deaths at age (x) the relevant age intervals are indicated in terms of age at last birthday. For the cumulated age distributions the upper *exact* age limit is indicated for each interval. The lower limit is age 0 in each instance.
Birth rate Death rate	Births and deaths of given sex per 1,000 persons of given sex, that is, intrinsic birth and death rates per 1,000.
Growth rate	Same as symbol R used in column headings and defined above.

[9] William Brass *et al. The Demography of Tropical Africa,* Princeton University Press, Princeton, N. J., 1968, Chapter 3.

GRR (29)	Gross reproduction rate for given sex when the mean age of the underlying maternity (or paternity) schedule is M years.
NRR (29)	Net reproduction rate for given sex when the mean age of the underlying maternity schedule is M years.
Percent 15-44	Number of people aged 15–44 in the stable population per 100 persons.
Brths/pop 15-44	Births of given sex per person of given sex aged 15–44. With reference to the female population, sometimes called the birth–woman ratio.
Pop <4/15-44	Persons of given sex aged 0–4 per person of 15–44 of given sex. With reference to the female population, sometimes called the child–woman ratio.
Depndcy ratio	Persons aged 0–14 and over 60 of given sex per person 15–59 of given sex. Sometimes called the dependency ratio.
Pop size/births	The reciprocal of the birth rate, that is, the size of the stable population for a unit-size current-year (year zero) birth cohort.
Exp of life	Expectation of life at birth in the life table identified in the table heading by pattern, level, and sex. This index is printed in the "GRR" set of tables only, in the last line under the first column.
DR over age 1	Death rate of persons above age 1, that is, deaths to persons over age 1 of given sex per 1,000 persons over age 1.
Avg age at dth	Average age at death in stable populations of given sex.
Avg age dth >5	Average age at death in stable population of given sex of persons dying at age 5 and over.
Deaths (30+/5+)	Deaths in stable populations to persons of given sex over 30 per death to persons of given sex over 5.

D. HINTS ABOUT USING THE TABLES

USE OF CUMULATIVE AGE DISTRIBUTION

The second table on each stable population page is a cumulative age distribution of the population; the fourth table is a cumulative age distribution of deaths. The cumulative age distributions make it possible to find the proportion of persons (or deaths) for various age intervals (e.g., 15–64) by a single subtraction.

IDENTIFICATION OF MORTALITY LEVELS UNDERLYING MODEL STABLE POPULATIONS

Underlying each of the 13 stable populations is a single life table identified on each page by the regional mortality pattern, sex, and mortality level in the upper left and upper right corners. Any desired characteristics of the corresponding life table (e.g., the value of infant mortality) is easily determined by consulting the table at the given level in the model life table section. Note, however, that a convenient cardinal measure of the underlying life table—the expectation of life at birth—can always be determined without reference to the life table section. In the "growth rate" set of stable age distributions this is performed by reference to the stationary age distribution—the age distribution when $r = 0$. The line labeled "Pop size/births" in the population indices at the bottom of the page is the reciprocal of the birth rate, which *for the stationary population* is also the expectation of life at birth of the corresponding life table. In the GRR set of tables the expectation of life at birth in the corresponding model life table is stated in the indices.

USE OF THE RECIPROCAL OF THE BIRTH RATE

The reciprocal of the birth rate printed in the tables for stable populations is, by definition, the size of the stable population expressed in terms of a unit-sized current birth cohort. Notice that this figure facilitates the calculations of a combined male and female stable age distribution implicit in the female fertility schedules, the male and female mortality schedules, and a sex ratio at birth.

Example. What is the sex ratio in the age group 10 years and over in a stable population with a female gross reproduction rate of 3.00 ($\bar{m} = 29$ years) if $e_0^\circ = 40.0$ years for females, if it is assumed that the age pattern and sex differentials of mortality are those characteristic of model "West" and the sex ratio at birth is 1.05?

The relevant mortality level for both sexes is Level 9. The size of the total female population over age 10 for one unit of "current" female births at GRR(29) = 3.00 is $22.479 \times (1 - .3005) = 15.724$. Similar calculation gives the male population as $21.370 \times (1 - .3051) = 14.850$. Since for each female birth there are 1.05 male births the answer to the question is given by the ratio of $(14.850 \times 1.05)/15.724 = 0.992$. Note that the figures for the male population are taken from a column identified by the level of the female GRR.

THE GRR FIGURES IN THE TABLES FOR MALE STABLE POPULATIONS

In the "growth rate" sets of tables for stable populations (populations with specified evenly spaced growth rates) the tables for males indicate the level of GRR calculated on the basis of the same "maternity" distribution used for the females, that is, with a mean age of 29 years. It should be kept in mind, however, that the mean age of the male fertility schedule is often several years greater than in the female schedule of the same population. Thus, there may be instances in which the GRR for males could be estimated only by a major adjustment, for high $\bar{m}$. But even with these reservations, we felt there will be occasions on which the male GRRs can prove useful.

In the GRR sets of tables the information on male gross reproduction rates was suppressed to avoid confusion. The GRR value that appears in the heading of these tables is, as the title of the tables indicate, a *female* GRR (with a mean of 29 years for the underlying maternity function). The association of this female GRR with the given male stable population is this: it would produce, jointly with the *female* mortality of the same level as the given male life table, a rate of increase equal to that shown for the male population.

ROUNDING OF FIGURES, INTERPOLATION

The last digit of all figures printed in the tables is rounded. Thus, a death rate of 19.218...is printed as 19.22 and so on.

The tabulation of both the life tables and stable population characteristics is sufficiently "dense" so that as a rule simple linear interpolation can be applied to obtain values intermediate between tabulated figures.

DISCREPANCIES ARISING FROM THE USE OF AGE INTERVALS OF FINITE WIDTH

The use of age intervals (0–1, 1–4, 5–9, etc.) is for most practical purposes a fine enough division to support calculations as accurate as is warranted in the light of available data, but we wish nonetheless to call attention to an instance where grouped data introduce biases. Population projection by use of the factor ${}_5L_{x+5}/{}_5L_x$ is based on an assumption that the age distribution within each five-year interval of the stationary population and the population being projected is the same. If the population projected is growing rapidly, there is a detectable difference between the actual survival rate for children born during the five-year projection interval, and the factor ${}_5L_0/5l_0$. (The latter is in this instance too small.) The next survival ratio—${}_5L_5/{}_5L_0$—is slightly too large for a growing population.

These effects imply, among other small-scale effects, that stable populations obtained by projection with five-year survival factors differ slightly from those printed here, which make allowance for subdivision within the first five years.

TABLE XIV. Values of l_x by single years of age from 1 to 5 for regional model life tables (l_0 = 100,000) at mortality levels 1–24
